HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers. L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
New Dry Friction Model with Load- and Velocity-Dependence and Dynamic Identification of Multi-DOF Robots

Abstract—Usually, the joint transmission friction model for robots is composed of a viscous friction force and of a constant dry sliding friction force. However, according to the Coulomb law, the dry friction force depends linearly on the load driven by the transmission, which has to be taken into account for robots working with large variation of the payload or inertial and gravity forces. Moreover, for robots actuating at low velocity, the Striebeck effect must be taken into account. This paper proposes a new inverse dynamic identification model for n degrees of freedom (dof) serial robot, where the dry sliding friction force is a linear function of both the dynamic and the external forces, with a velocity-dependent coefficient. A new sequential identification procedure is carried out. At a first step, the friction model parameters are identified for each joint (1 dof), moving one joint at a time (this step has been validated in [23]). At a second step, these values are fixed in the n dof dynamic model for the identification of all robot inertial and gravity parameters. For the two steps, the identification concatenates all the joint data collected while the robot is tracking planned trajectories with different payloads to get a global least squares estimation of inertial and new friction parameters. An experimental validation is carried out with an industrial 3 dof robot.

I. INTRODUCTION

The usual identification method is based on the inverse dynamic model (IDM) which is linear in relation to the dynamic parameters, and uses least squares (LS) technique. This procedure has been successfully applied to identify inertial and friction parameters of a lot of prototypes and industrial robots [1]-[10]. An approximation of the sliding Coulomb friction, \( F_c \cdot \text{sign}(q) \), is widely used to model friction force at non zero velocity \( \dot{q} \), assuming that the friction force \( F_c \) is a constant parameter. It is identified by moving the robot without any load (or external force) or with constant given payloads [9].

However, the Coulomb law suggests that \( F_c \) depends on the transmission force driven in the mechanism. It depends on the dynamic and on the external forces applied through the joint drive chain. Consequently for robots with varying load, the identified IDM is no more accurate when the transmission uses industrial speed reducer, screw-nut or worm gear because their efficiency significantly varies with the transmitted force. The significant dependence on load has been often observed for transmission elements [15]-[19] through direct measurement procedures. Moreover, the mechanism efficiency depends on the sense of power transfer leading to two distinct sets of friction parameters. In addition, when the robot moves at very low velocity, as for teleoperation, one observes a velocity-dependence of the dry friction.

This paper presents a new inverse dynamic identification model for n degrees of freedom (dof) serial robot, where the dry sliding friction force \( F_c \) is a linear function of both the dynamic and the external forces, with asymmetrical behavior depending on the signs of joint force and velocity, and a variation depending on the velocity amplitude. A new identification procedure is proposed. All the joint position and joint force data collected in several experiments, while the robot is tracking planned trajectories with different payloads, are concatenated to calculate a global least squares estimation of both the inertial and the new friction parameters.

An experimental validation is carried out on the 3 first joints of the Stäubli TX40 industrial robot [26].

II. USUAL INVERSE DYNAMIC MODELING AND IDENTIFICATION

A. Modeling

In the following, all mechanical variables are given in SI units in the joint space. All forces, positions, velocities and accelerations have a conventional positive sign in the same direction. That defines a motor convention for the mechanical behavior.

The dynamic model of a rigid robot composed of \( n \) moving links is written as follows [11]:

\[
\tau_{\text{dyn}} = \tau + \tau_f + \tau_{\text{off}} + \tau_{\text{ext}} 
\]

(1)

where:

- \( \tau_{\text{dyn}} \) is the (nx1) vector of dynamic forces due to the inertial, centrifugal, Coriolis, and gravitational effects:

\[
\tau_{\text{dyn}} = M(q)\ddot{q} + C(q, \dot{q})\dot{q} + Q(q) 
\]

(2)

where \( q, \dot{q} \) and \( \ddot{q} \) are respectively the (nx1) vectors of generalized joint positions, velocities and accelerations, \( M(q) \) is the (nxn) robot inertia matrix, \( C(q, \dot{q}) \) is the (nxn) matrix of centrifugal and Coriolis effects, \( Q(q) \) is the (nx1)
vector of gravitational forces.
- \( \tau \) is the \((nx1)\) input torque vector on the motor side of
  the drive chain, without offset:
  \[
  \tau = g_f v_f
  \]  
  (3)
where \( v_f \) is the \((nx1)\) vector of current references of the
current amplifiers, \( g_f \) is the \((nxn)\) matrix of the drive gains.
- \( \tau_f \) is the \((nx1)\) vector of the loss force due to viscous
  and dry frictions, without offset:
  \[
  \tau_f = -F_v \dot{q} - F_c \text{sign}(\dot{q})
  \]  
  (4)
where \( F_v \) is the \((nxn)\) diagonal matrix of viscous parameters,
\( F_c \) is the \((nxn)\) diagonal matrix of dry friction parameters,
and \( \text{sign}(\cdot) \) denotes the sign function (Fig. 1.a).
- \( \tau_{\text{off}} \) is an offset force that regroups the amplifier offset
  and the asymmetrical Coulomb friction coefficient.
- \( \tau_{\text{ext}} \) is the \((nx1)\) external forces vector in the joint space.

Then (1) can be rewritten as the inverse dynamic model (IDM) which calculates the motor torque vector \( \tau \) as a function of the generalized coordinates:
\[
\tau = M(q) \ddot{q} + C(q, \dot{q}) \dot{q} + Q(q) + F_v \text{sign}(\dot{q}) + F_c \dot{q} + \tau_{\text{off}} - \tau_{\text{out}}
\]  
(5)
where \( \tau_{\text{out}} = \tau_{\text{dyn}} - \tau_{\text{ext}} \) is the output force (the load force) of
the drive chain. For more details, see [23]

B. Identification

The choice of the modified Denavit and Hartenberg frames attached to each link allows to obtain a dynamic model linear in relation to a set of standard dynamic parameters \( \chi \) [6], [11]:
\[
\tau = D_S(q, \dot{q}, \ddot{q}) \chi
\]  
(6)
where \( D_S(q, \dot{q}, \ddot{q}) \) is the regressor and \( \chi \) is the vector of
the standard parameters which are the coefficients \( XX_p, XY_p, XZ_p, Y_1, Y_2, Z_2 \) of the inertia tensor of link \( j \) denoted \( \mathcal{M}_j \), the mass
of the link \( j \) called \( m_j \), the first moments vector of link \( j \) around
the origin of frame \( j \) denoted \( \mathbf{M}_j = [Mx_M, My_M, Mz_M]^T \),
the friction coefficients \( F_v, F_c \), the actuator inertia called
\( I_a \), and the offset \( \tau_{\text{off}} \). The velocities and accelerations are calculated using well tuned band pass filtering of the joint position [7].

The base parameters are the minimum number of parameters from which the dynamic model can be calculated. They are obtained by eliminating and by regrouping some standard inertial parameters [12], [13]. The minimal inverse dynamic model can be written as:
\[
\tau = D(q, \dot{q}, \ddot{q}) \chi
\]  
(7)
where \( D(q, \dot{q}, \ddot{q}) \) is the minimal regressor and \( \chi \) is the vector
of the base parameters.

The inverse dynamic model (7) is sampled while the robot is tracking a trajectory to get an over-determined linear system such that [6]:
\[
Y(\tau) = W(q, \dot{q}, \ddot{q}) \chi + \rho
\]  
(8)
with \( Y(\tau) \) the measurements vector, \( W \) the observation matrix and \( \rho \) the vector of errors.

The LS solution \( \hat{\chi} \) minimizes the 2-norm of the vector of
errors \( \rho \). \( W \) is a \((r \times b)\) full rank and well conditioned matrix
where \( r = N \times n \), with \( N \) the number of samples on the trajectories. The LS solution \( \hat{\chi} \) is given by:
\[
\hat{\chi} = \left(W^T W\right)^{-1} W^T Y = W^T Y
\]  
(9)
It is calculated using the QR factorization of \( W \). Standard deviations \( \sigma_{\chi} \) are estimated using classical and simple results from statistics. The matrix \( W \) is supposed to be deterministic, and \( \rho \), a zero-mean additive independent noise,
with a standard deviation such as:
\[
C_{\rho \rho} = \text{E}(\rho \rho^T) = \sigma_{\rho}^2 I_r
\]  
(10)
where E is the expectation operator and \( I_r \), the \((r \times r)\) identity matrix. An unbiased estimation of \( \sigma_{\rho} \) is:
\[
\hat{\sigma}_{\rho}^2 = \frac{\|Y - W \hat{\chi}\|^2}{(r-b)}
\]  
(11)

The covariance matrix of the standard deviation is calculated as follows:
\[
C_{\hat{\chi}} = \text{E}[(\chi - \hat{\chi})(\chi - \hat{\chi})^T] = \sigma_{\rho}^2 (W^T W)^{-1}
\]  
(12)
\[
\sigma_{\hat{\chi_i}}^2 = C_{\hat{\chi_i} \hat{\chi_i}}
\]

The relative standard deviation \( \% \sigma_{\hat{\chi_i}} \) is given by:
\[
\% \sigma_{\hat{\chi_i}} \hat{\chi_i} = 100 \sigma_{\hat{\chi_i}} / \hat{\chi_i}
\]  
(13)
However, experimental data are corrupted by noise and error modeling and \( W \) is not deterministic. This problem can be solved by filtering the measurement vector \( Y \) and the columns of the observation matrix \( W \) as described in [7], [8].

III. NEW DRY FRICTION MODEL AND IDENTIFICATION

In this section, we introduce a dry friction model dependent on the load, that is \( \tau_{\text{out}} \), and on the velocity \( \dot{q} \).
This model is more detailed in [23] (see also [24]).

A. Load- and Velocity-Dependent Friction Model

The Coulomb friction is still written \( F_c \text{sign}(\dot{q}) \), with \( F_c \) a
\((nxn)\) diagonal matrix.

But here, for each link \( j \), \( F_{cj} \) (the \((j, j)\)th element of the
matrix \( F_c \)) depends linearly on the absolute value of the
load of joint $j$ which is $\tau_{out,j}$ (Fig. 1.b), [15]-[19]:

$$F_{c,j} = \alpha_j |\tau_{out,j}| + \beta_j$$  \hspace{1cm} (14)

At low velocity, taking into account the Stribeck effect improves the model accuracy, [20]-[22]:

$$F_{c,j} = F_{s,j} + (F_{s,j} - F_{s,j})e^{\frac{\dot{q}_j}{\gamma_j}}$$  \hspace{1cm} (15)

where $\dot{q}_j$ is a velocity constant, $F_{s,j}$ is the dry friction in stiction and $F_{s,j}$ is the dry friction in sliding mode.

To combine both load (14) and velocity (15) variations one takes:

$$F_{s,j} = \alpha_j |\tau_{out,j}| + \beta_j$$ and $F_{s,j} = \gamma_j |\tau_{out,j}| + \delta_j$  \hspace{1cm} (16)

Then, the dry friction model becomes (Fig. 1.c):

$$F_{c,j} = \alpha_j |\tau_{out,j}| + \beta_j + (\gamma_j |\tau_{out,j}| + \delta_j - \alpha_j |\tau_{out,j}| - \beta_j)e^{\frac{\dot{q}_j}{\gamma_j}}$$  \hspace{1cm} (17)

where $\alpha_j$, $\beta_j$, $\gamma_j$, and $\delta_j$ are to be identified. These new parameters depend on the mechanical structure of the reducers used to actuate the robot.

To simplify, by using $|\tau_{out,j}| = \tau_{out,j} \text{sign}(\tau_{out,j})$ and $\text{sign}(\tau_{out,j})\text{sign}(\dot{q}_j) = \text{sign}(|\tau_{out,j}|\dot{q}_j) = \text{sign}(P_{out,j})$, one obtains:

$$F_{c,j}\text{sign}(\dot{q}_j) = \left(\alpha_j + (\gamma_j - \alpha_j)e^{\frac{\dot{q}_j}{\gamma_j}}\right)\tau_{out,j}\text{sign}(P_{out,j}) + \left(\beta_j + (\delta_j - \beta_j)e^{\frac{\dot{q}_j}{\gamma_j}}\right)\text{sign}(\dot{q}_j)$$  \hspace{1cm} (18)

For each joint, the frame $(\dot{q}_j, \tau_{out,j})$ is divided in 4 quadrants which can be grouped two by two (Fig. 2.a). In the quadrants 1 and 3, the output power $P_{out,j}$ is positive and the actuator has a motor behavior. In the quadrants 2 and 4, $P_{out,j}$ is negative and the actuator has a generator behavior.

In the model (18), $\alpha_j$, $\beta_j$, $\gamma_j$ and $\delta_j$ take generally different values depending on the actuator behavior: $\alpha_{m,j}$, $\beta_{m,j}$, $\gamma_{m,j}$ and $\delta_{m,j}$ for the motor quadrants, and $\alpha_{g,j}$, $\beta_{g,j}$, $\gamma_{g,j}$ and $\delta_{g,j}$ for the generator quadrants. See Fig. 2b: illustration of (19) with (14) for a constant velocity $|\dot{q}_g|$, and 2 different sets of friction parameters (motor and generator), in frame $(\tau, \tau_{out})$.

For each joint $j$, the dynamic model can be written as follows:

$$\tau_j = \tau_{out,j} + F_{c,j}\text{sign}(\dot{q}_j) + F_{v,j}\dot{q}_j + \tau_{off,j}$$  \hspace{1cm} (19)

Considering $a_{m,j} = \tau_{m,j} - \alpha_{m,j}$, $b_{m,j} = \delta_{m,j} - \beta_{m,j}$, $a_{g,j} = \gamma_{g,j} - \alpha_{g,j}$, and $b_{g,j} = \delta_{g,j} - \beta_{g,j}$, the inverse dynamic model for joint $j$ is written with 2 expressions and becomes:

$$\begin{align*}
\text{if } P_{out,j} > 0 & \Rightarrow \tau_j = (1 + a_{m,j})\tau_{out,j} + a_{m,j}\tau_{out,j}e^{\frac{\dot{q}_j}{\gamma_j}} + ... + b_{m,j}\text{sign}(\dot{q}_j) + b_{m,j}\text{sign}(\dot{q}_j) + F_{v,j}\dot{q}_j + \tau_{off,j} \\
\text{if } P_{out,j} < 0 & \Rightarrow \tau_j = (1 - a_{g,j})\tau_{out,j} - a_{g,j}\tau_{out,j}e^{\frac{\dot{q}_j}{\gamma_j}} + ... + b_{g,j}\text{sign}(\dot{q}_j) + b_{g,j}\text{sign}(\dot{q}_j) + F_{v,j}\dot{q}_j + \tau_{off,j}
\end{align*}$$  \hspace{1cm} (20)

### B. Friction Identification Method

In order to keep a model linear in relation to the parameters and to use the linear least square method, one has an identification in 3 steps.

At a first step, $\dot{q}_j$ is identified with the measurements of several constant velocities trajectories: the amplitude of the transitional behavior, on the graph of the mean input torque with respect to the mean velocity (Fig. 4), is 3 times $\dot{q}_j$.

One introduces a new variable $E_{sp,j}$, defined by:

$$E_{sp,j} = e^{\frac{\dot{q}_j}{\gamma_j}}$$  \hspace{1cm} (21)

At a second step, one identifies each joint separately to obtain especially the values of the friction parameters of each joint. However, the model (20) depends on the sign of $P_{out,j}$ which is unknown. To overcome this problem, the samples of $\tau$ measurements are selected outside of the dissipative area (Fig. 2b) in order to get the same sign for $\tau_{out,j}$ and $\tau_j$.

This allows to get the sign of $P_{out,j}$ with:

$$\begin{align*}
\text{sign}(P_{out,j}) = \text{sign}(\tau_{out,j})\dot{q}_j = \text{sign}(\tau_j\dot{q}_j) = \text{sign}(P_j)
\end{align*}$$  \hspace{1cm} (22)

One can then write the IDM linear in relation to parameters and use the LS technique. To have only one
expression instead of two in (20), 2 variables are introduced, \( P_j^+ \) and \( P_j^- \) defined by:

\[
P_j^+ = \frac{1 + \text{sign}(P_j)}{2}, \quad P_j > 0 \Leftrightarrow P_j^+ = 1, \quad P_j < 0 \Leftrightarrow P_j^- = 0 \quad (23)
\]

\[
P_j^- = \frac{1 - \text{sign}(P_j)}{2} = P_j^*
\]

The inverse dynamic model of joint \( j \) is then written:

\[
\tau_j = P_j^*(I + \alpha_{m_j} + a_{m_j} E_{\dot{q}_j}) \tau_{\text{out}_j} + P_j^*(I - \alpha_{g_j} - a_{g_j} E_{\dot{q}_j}) \tau_{\text{out}_j} + \ldots
\]

\[
\ldots P_j^* (\beta_{m_j} + b_{m_j} E_{\dot{q}_j}) \text{sign}(\dot{q}_j) + P_j^* (\beta_{g_j} + b_{g_j} E_{\dot{q}_j}) \text{sign}(\dot{q}_j) + \ldots \quad (25)
\]

\[
\ldots F_j \dot{q}_j + \tau_{\text{eff}_j}
\]

\( \tau_{\text{out}_j} \) is linear in relation to inertial and gravity parameters and can be written \( \tau_{\text{out}_j} = D_{\text{out}_j} \vec{x}_{\text{out}_j} \). For a known value \( \dot{q}_{Sj} \) (from step 1), the variable (21) allows to obtain a linear identification model (25) where the parameters to identify are: \( (I + \alpha_{m_j}) \vec{x}_{\text{out}_j}, \ a_{m_j} \vec{x}_{\text{out}_j}, \ (I - \alpha_{g_j}) \vec{x}_{\text{out}_j}, \ a_{g_j} \vec{x}_{\text{out}_j}, \) and all the friction parameters alone. By using exciting trajectories and the LS technique, one can then obtain the values of \( \alpha_{m_j}, \ a_{m_j}, \ \alpha_{g_j}, \ and \ a_{g_j}. \)

The same method, with products of parameters to have a linear model, is hard to apply to a multi-dof robot as the number of parameters to identify would increase a lot with the number of joints (for example, with the 3 dof robot here: 15 parameters for the usual model will give 67 parameters for the new one). That is why the second step is needed to identify the friction parameters alone, and set their values for the third step: the multi-dof identification.

At a third step, the values of \( \dot{q}_{Sj}, \ \alpha_{m_j}, \ a_{m_j}, \ \alpha_{g_j}, \) and \( a_{g_j} \) of each joint are added in the global observation matrix of the robot \( W \). Then, the global inverse dynamic model is linear in relation to inertial and gravity parameters, and to the parameters \( \beta_{m}, \ b_{m}, \ \beta_{g}, \ b_{g}, \ F_j \) (which are all (nxn) diagonal matrices) and \( \tau_{\text{eff}_j} \). All these parameters can be identified.

IV. EXPERIMENTAL SETUP AND IDENTIFICATION

Fig. 3. The Staubli TX40 Robot: picture without payload, picture with 1.195 kg payload, and drawing with frame for each joint.

A. Study case: Staubli TX40 Robot

The Stäubli TX40 robot (Fig. 3) is an industrial robot with 6 rotational joints. The 3 first joints are studied here and the links 4, 5 and 6 are locked in position 0.

The nominal velocity is 5.01 rad/s for the joints 1 and 2, and 7.52 rad/s for the joint 3. The maximum acceptable load at the extremity is about 2 kg.

B. Data Acquisition

The identification of dynamic parameters is carried out with and without payloads: five different additional masses can be fixed to the arm extremity. To excite properly the friction parameters to be identified, sinusoidal and trapezoidal velocities trajectories were used.

The estimation of \( \dot{q} \) and \( \ddot{q} \) are carried out with pass band filtering of \( q \) consisting of a low pass Butterworth filter and a central derivative algorithm. The Matlab function \texttt{filtfilt} can be used [25]. The motor torque is calculated using the current reference (3). In order to cancel high frequency ripple in \( \tau \), the vector \( Y \) and the columns of the observation matrix \( W \) are both low pass filtered and decimated. This parallel filtering procedure is carried out with the Matlab \texttt{decimate} function [2], [10].

C. First Identification Step

As the Strubeck effect is increased when the joint is loaded, one takes for each joint the measurements with the highest load (positive and negative) and for several constant velocities (positive and negative) to observe the amplitude of the exponential transient behavior. For each joint, \( \dot{q}_{Sj} \) is measured on the graph of the input torque functions of the velocity (Fig. 4):

\[
\dot{q}_{Sj} = 0.1, \quad \dot{q}_{Sj} = 0.1, \quad \text{and} \quad \dot{q}_{Sj} = 0.15.
\]

D. Second Identification Step

Each joint \( j \) is identified alone to obtain the values of \( \alpha_{m_j}, \ a_{m_j}, \ \alpha_{g_j}, \) and \( a_{g_j}. \) To identify the load-dependent friction, measurements with known payloads are used and the robot...
configuration is chosen so that the load variation is bigger. Gravity and inertial forces due to the additional mass fixed to the robot extremity have to be added in the IDM. Details are given for the joint 2: the measurements are done with the link 3 aligned with link 2 (all links are locked except for the 2nd).

And the inverse dynamic model of joint 2 is given by:

$$\tau_2 = J_2 \ddot{q}_2 + \tau_{\text{r}_2} = M_{a2} L_{a2} \ddot{q}_2 + g \cos(q_2) + \tau_{\text{r}_2}$$

where:
- \( J_2 = I_{a2} + ZZ_{R2} \) is the inertia moment \( I_{a2} \) of the drive chain plus the inertia moment \( ZZ_{R2} \) of the arm,
- \( ZZ_{R2}, MX_{R2}, MY_{R2} \) are the inertial parameters of link 2 regrouped with those of link 3 to 6 which are locked,
- \( g = 9.81 \text{ m/s}^2 \) is the gravity acceleration,
- \( M_{a2} (k \in [1 : 5]) \) is the mass of one of the five additional payloads, with accurate weighed values: 0.00 kg, 0.6744 kg, 1.1955 kg, 1.6990 kg, and 2.2173 kg,
- \( L_{a2} \) is the length from the joint 2 to the gravity center of the mass of the additional payload (measured distances): 0.00 m, 0.5335 m, 0.5395 m, 0.5465 m, and 0.5415 m.

All variables and parameters are given in SI units on the joint space.

One defines \( \tau_{\text{r}_2} \) which is the output torque due to the additional payload \( k \), applied on joint 2:

$$\tau_{\text{r}_2} = \left( I_{a2} + \sum_{k=1}^{5} M_{a2} \right) \ddot{q}_2 + g \cos(q_2) + \tau_{\text{r}_2}$$

Then, \( \tau_{\text{r}_2} \) is defined by:

$$\tau_{\text{r}_2} = J_2 \ddot{q}_2 + MX_{R2} \cos(q_2) + MY_{R2} \sin(q_2) + \tau_{\text{r}_2}$$

and the IDM of joint 2 with the proposed friction model is written as in (25):

$$\tau_2 = \left( P^+_1 (l + \alpha_{a2} + a_{a2} E_{q_{a2}}) + P^+_2 (l - \alpha_{a2} - a_{a2} E_{q_{a2}}) \right) \ddot{q}_2 + ...$$

$$\tau_{\text{r}_2} = \left( P^+_1 (\beta_{a2} + b_{a2} E_{q_{a2}}) \right) \ddot{q}_2 + ...$$

One takes a linear form of this IDM and it is identified (a comparison of the results can be made with the usual friction model but is not detailed here. See [23]). The sampled measurements, for \( k \) from 1 to 5, are concatenated using the \( \tau_{\text{r}_2} \) corresponding to all experiments \( k \) with the motor torques \( \tau_{\text{r}_2} \), to get the linear system:

$$Y_2 = W_2 X_2 + \rho_2$$

with the measurements vector, the observation matrix, and the vector of base parameters defined as follows:

$$Y_2 = \tau_2 = \begin{bmatrix} \tau_{\text{r}_2} \tau_{\text{r}_2} \tau_{\text{r}_2} \tau_{\text{r}_2} \tau_{\text{r}_2} \end{bmatrix}^T$$

$$W_2 = \begin{bmatrix} P^+_1 \tau_{\text{r}_2} \ P^+_1 E_{q_{a2}} \tau_{\text{r}_2} \ P^+_1 \cos(q_2) \tau_{\text{r}_2} \\ \vdots \vdots \vdots \vdots \vdots \vdots \end{bmatrix}$$

$$\rho_2 = \begin{bmatrix} \tau_{\text{r}_2} \tau_{\text{r}_2} \tau_{\text{r}_2} \tau_{\text{r}_2} \tau_{\text{r}_2} \end{bmatrix}^T$$

where:
- \( \tau_{\text{r}_2} \) is the output torque due to the additional payload \( k \), applied on joint \( j \). This torque is calculated thanks to known inertial and gravity parameters obtained by masses.
and dimensions measurements and CAD. Thus, each $\tau_{maj}$ depends on the additional mass and on the positions, velocities and accelerations of all joints.

One identifies first the usual model. The minimal inverse dynamic model is the same as in (7), except that one adds a column in the minimal regressor $D$, and 4 parameters in $\chi$:

$$D_{\text{usual}} = \begin{bmatrix} \tau_{maj} & 0 & 0 \\ D & 0 & \tau_{maj} \\ 0 & 0 & \tau_{maj} \end{bmatrix}$$  \hspace{1cm} (35)$$

$$\chi_{\text{usual}} = \begin{bmatrix} \chi^T \ One_1 \ One_2 \ One_3 \end{bmatrix}^T$$  \hspace{1cm} (36)

with $One_j = \frac{\tau_{maj}}{\tau_{maj}}$, where $\tau_{maj}$ is the estimation of the torque $\tau_{maj}$ by the identification. If the model is well identified, each parameter $One_j$ should be found close to one.

Then, one identifies the proposed model. The minimal inverse dynamic model is written from the usual one. At a first stage, one modifies the minimal regressor with the friction coefficients identified in step 2:

$$D_{\text{new}(j,k)} = \left( P_j (I + \alpha_j + \alpha_g E_{q_j} + \alpha_j E_{q_j}) + P_j (I - \alpha_j - \alpha_g E_{q_j}) \right) D_{\text{usual}(j,k)}$$ \hspace{1cm} (37)

if $\chi_k$ is an inertial or a gravity parameter (that is to say one of the $XX$, $XY$, $XZ$, $YY$, $YZ$, $ZZ$, $MX$, $MY$, $MZ$, $m$, $Ia$, or $One$).

$$D_{\text{new}(j,k)} = D_{\text{usual}(j,k)}$$ otherwise.

At a second stage, one deals with the other friction parameters: the parameters $F_{ij}$ and their corresponding columns in $D_{\text{new}}$ are first removed. Then instead, one adds the parameters $\beta_{ij}$, $b_{ij}$, $\beta_i$, and $b_i$ and their corresponding columns in $D_{\text{new}}$:

- if $\beta_{ij}$ is the $k^{th}$ parameter in $\chi_{\text{new}}$, then the column $k$ of $D_{\text{new}}$ is defined as follows:

$$D_{\text{new}(j,k)} = \begin{cases} 0 & \text{if } k \neq j \\ P_j^T \text{sign}(q_j) & \text{if } k = j \end{cases}$$ \hspace{1cm} (38)

- if $b_{ij}$ is the $k^{th}$ parameter in $\chi_{\text{new}}$, then the column $k$ of $D_{\text{new}}$ is defined as follows:

$$D_{\text{new}(j,k)} = \begin{cases} 0 & \text{if } k \neq j \\ P_j^T E_{q_j} \text{sign}(q_j) & \text{if } k = j \end{cases}$$ \hspace{1cm} (39)

- if $\beta_i$ is the $k^{th}$ parameter in $\chi_{\text{new}}$, then the column $k$ of $D_{\text{new}}$ is defined as follows:

$$D_{\text{new}(j,k)} = \begin{cases} 0 & \text{if } k \neq j \\ P_j^T \text{sign}(q_j) & \text{if } k = j \end{cases}$$ \hspace{1cm} (40)

- if $b_i$ is the $k^{th}$ parameter in $\chi_{\text{new}}$, then the column $k$ of $D_{\text{new}}$ is defined as follows:

$$D_{\text{new}(j,k)} = \begin{cases} 0 & \text{if } k \neq j \\ P_j^T E_{q_j} \text{sign}(q_j) & \text{if } k = j \end{cases}$$ \hspace{1cm} (41)

For this model too, the parameters $One_j$ should be found close to one. Both models are compared using the same measurements and the LS technique.

**F. Results**

The significant values identified with usual IDM and OLS regressions are given in Table 3 and those with the new IDM in Table 4 (the parameters with a large relative deviation are not significant and have been eliminated). Moreover, Table 5 presents the relative norm of errors $\|\hat{p}\|/\|p\|$ and the standard deviation for the two models.

</table>
For each model and each joint, one plots a direct validation comparing the actual $\tau$ with its predicted value $\tilde W \hat \tau$. The graphs Fig. 6 and Fig. 7 show the input torque for movements done with the payload of 2.2173 kg and with trajectories described by the graphs of the velocities Fig. 5: velocities between 40% and 80% of the nominal velocity for joint 1, velocity at 0.5% of the nominal velocity for joint 2, and velocities between 2% and 6% of the nominal velocity for joint 3. The graphs Fig. 6 are obtained for the usual model and the graphs Fig. 7 for the new model: the measured input torque is plotted in black, the estimated torque is plotted in light-gray and the error is plotted in dark-gray.

### Table 5: Models Comparison

<tr>
<td>Usual Model</td>
<td>0.08913</td>
</tr>
<tr>
<td>New Model</td>
<td>0.07042</td>
</tr>
</tbody>
</table>

The parameters of both models are identifiable (low standard deviation). The parameters $\hat \alpha_i$, are close to one which means that the additional payloads are well-identified by the models. As one can see in Table 5, the relative norm of error for the global identification is low. One observes a decrease of 20% in the relative norm of errors between the usual model and the new one. This difference is not very large because all measurements were used for the global identification: low and high velocities and low and high masses for the payload. The improvement is mostly important for low velocities and high load variation, whereas the models are equivalent at high velocity and low load variation.

The joint 1 has no load variation due to gravity, as it is vertical. Thus, the new model will be useful for the joint 1 at very low velocities (Stibbeck effect) or when there are inertial variations: Fig. 6 and Fig. 7 show the input torque for a movement with high accelerations and velocities.
One sees an improvement especially for the highest velocity. For the joint 2, Fig. 6 and Fig. 7 presents a comparison between the models, and for a movement at very low velocity, to show the improvement due to the modeling of the Strieber effect. When the velocity increases, the improvement decreases but there is still an improvement with the new model due to the load-dependence. This one is not so important for the joint 2, as for the joint 3, as one can see in the Table 2: the parameters $\alpha_{m2}$ and $\alpha_{s2}$ are closer to 0 than the parameters $\alpha_{m3}$ and $\alpha_{s3}$.

For the joint 3, one observes (Fig. 6 and Fig. 7) an important improvement thanks to the modeling of the load-dependence of friction. This modeling is very important at low velocity as the dry friction is predominant.

The identification of the new model is carried out with three steps, is more time-consuming and the setting up must be adapted for the measurements with additional masses. However, this model is valid for all type of movement: low and high velocities, low and high loads. For some movements, it is equivalent to the usual model, whereas for others (low velocities or high load variation), it brings a real improvement.

The proposed model is important for example in teleoperation, where the robots work at reduced velocity and can carry payloads or perform tasks with the effector subjected to external forces.

VI. CONCLUSION

This paper has presented a new dry friction model, with load- and velocity-dependence, and its identification method for a multi-dof robot. The inverse dynamic model and the identification of its parameters have been successfully validated on the 3 first joints of an industrial robot. As a result, one observes an improvement comparing to the usual model, for movements with large load variations and for movements at low velocity. Robots carrying important masses or with large inertial or gravity variations are concerned. The field of applications for which the new model can be very interesting is the telerobotics.

Future works concern the application of this model to slave robots for teleoperation and the use for torques monitoring and collision detection.
