HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

Many-Body-Localization Transition : strong multifractality spectrum for matrix elements of local operators

Cécile Monthus

Institut de Physique Théorique, Université Paris Saclay, CNRS, CEA, 91191 Gif-sur-Yvette, France

For short-ranged disordered quantum models in one dimension, the Many-Body-Localization is analyzed via the adaptation to the Many-Body context [M. Serbyn, Z. Papic and D.A. Abanin, PRX 5, 041047 (2015)] of the Thouless point of view on the Anderson transition : the question is whether a local interaction between two long chains is able to reshuffle completely the eigenstates (Delocalized phase with a volume-law entanglement) or whether the hybridization between tensor states remains limited (Many-Body-Localized Phase with an area-law entanglement). The central object is thus the level of Hybridization induced by the matrix elements of local operators, as compared with the difference of diagonal energies. The multifractal analysis of these matrix elements of local operators is used to analyze the corresponding statistics of resonances. Our main conclusion is that the critical point is characterized by the Strong-Multifractality Spectrum $f(0 \leq \alpha \leq 2) = \frac{\alpha}{2}$, well known in the context of Anderson Localization in spaces of effective infinite dimensionality, where the size of the Hilbert space grows exponentially with the volume. Finally, the possibility of a delocalized non-ergodic phase near criticality is discussed.

I. INTRODUCTION

In disordered interacting quantum systems, the Many-Body-Localization Transition (see the recent reviews [1, 2] and references therein) can be seen as a phase transition for the energy levels and for the excited eigenstates. In the Ergodic phase where the Eigenstate Thermalization Hypothesis (E.T.H.) [3–7] holds, the energy levels are governed by the Wigner-Dyson statistics, while the eigenstates display the volume-law entanglement with a prefactor given by the thermal entropy. In the Many-Body-Localized (MBL) phase, the energy levels are governed by the Poisson statistics, while the eigenstates display an area-law entanglement [8–12] allowing in particular efficient tensor networks representations [13–17]. The Strong Disorder Real-Space RG approach (see [18, 19] for reviews) developed initially by Ma-Dasgupta-Hu [20] and Daniel Fisher [21–23] to construct the ground states of random quantum spin chains, has been extended for the whole Many-Body-Localized phase into the Strong Disorder RG procedure for the unitary dynamics [24, 25], and into the RSRG-X procedure to construct the whole set of excited eigenstates [26–30]. This construction is possible only because the Many-Body-Localized phase is characterized by an extensive number of emergent localized conserved operators [33–41]. As a consequence, the Strong Disorder RG breaks down when the MBL transition towards delocalization is approached, and other types of real-space RG have been proposed for the critical point, based on the notion of insulating or thermalizing blocks of various sizes [42–44] and are in favor of a direct transition towards the ergodic phase. Then, as a consequence of the strong-subadditivity property of the entanglement entropy [45], the critical point itself has to satisfy the E.T.H. property, i.e. the entanglement entropy has to coincide with the thermal entropy [45]. However, another possibility is that the transition is towards a delocalized non-ergodic phase, i.e. the entanglement entropy satisfies the volume law, but not with the thermal coefficient fixed by the E.T.H. [45, 46]. This delocalized non-ergodic scenario is usually explained within the point of view that the MBL transition is somewhat similar to an Anderson Localization transition in the Hilbert space of ‘infinite dimensionality’ as a consequence of the exponential growth of the size of the Hilbert space with the volume [47–53]. Note however that the existence of a non-ergodic delocalized phase remains very controversial even for Random-Regular-Graphs that are locally tree-like without boundaries, as shown by the two very recent studies with opposite conclusions [54, 55]. In summary, whereas the Many-Body-Localized Phase seems nowadays well understood, there remains open issues concerning both the nature of the critical point and the nature of the delocalized phase (ergodic or non-ergodic) close to the critical point.

To characterize the MBL transition, Reference [56] has proposed recently to adapt to the Many-Body context the Thouless point of view for the Anderson transition : the question is whether a local interaction between two long chains is able to reshuffle completely the eigenstates or not [56]. This yields that the statistical properties of the matrix elements of local operators play an essential role [56], as also shown by the adaptation of the Dyson Brownian motion to Many-Body-Localization models [57, 58]. These studies have also suggested that multifractality is the good framework to describe these statistical properties [56–58]. The goal of the present work is thus to analyze in details the problem of the coupling between two long chains via the multifractal formalism.

The paper is organized as follows. In Section II, the coupling of two long chains via some local operator is described to introduce the notations. In Section III, the statistical properties of the matrix elements of local operators are analyzed via the multifractal formalism. In Section IV, the consequences for the multifractal statistics of the Hybridization

Ratios are derived. The conclusions are summarized in section V.

II. ANALYSIS OF THE LOCAL COUPLING BETWEEN TWO LARGE BLOCKS

A. Effects of the local coupling in the tensor-basis

Let us consider a disordered quantum spin chain model with nearest-neighbor interactions, with two independent large blocks of length N : the block A contains N quantum spins $i = 1, \dots, N$ and $M = 2^N$ energy levels a_i , while the block B contains N quantum spins $j = N + 1, \dots, 2N$ and $M = 2^N$ energy levels b_i , with the corresponding spectral decomposition

$$\begin{aligned} H_A &= \sum_{i=1}^M a_i |a_i\rangle\langle a_i| \\ H_B &= \sum_{j=1}^M b_j |b_j\rangle\langle b_j| \end{aligned} \quad (1)$$

The level spacing in each block is given at exponential level by the inverse of the size of the Hilbert space

$$\Delta_A = \Delta_B = \frac{1}{M} = 2^{-N} \quad (2)$$

Let us now introduce the local coupling between the spins $i = N$ and $J = N + 1$ that are at the boundaries of the two blocks. To be more concrete, let us consider the explicit case of the coupling via the local magnetization

$$V^{AB} = J_{AB} \sigma_N^x \sigma_{N+1}^x \quad (3)$$

The full Hamiltonian

$$H = H_A + H_B + V^{AB} \quad (4)$$

with an Hilbert space of size $\mathcal{M} = M^2 = 2^{2N}$, i.e. with the level spacing

$$\Delta_{AB} = \frac{1}{\mathcal{M}} = \frac{1}{M^2} \quad (5)$$

can be analyzed in the tensor-basis with $i = 1, \dots, M$ and $j = 1, \dots, M$.

$$|\phi_{ij}\rangle \equiv |a_i\rangle \otimes |b_j\rangle \quad (6)$$

via the matrix elements

$$\langle \phi_{i'j'} | H | \phi_{ij} \rangle = (a_i + b_j) \delta_{i,i'} \delta_{j,j'} + V_{i'j',ij}^{AB} \quad (7)$$

where the matrix elements of the coupling V^{AB}

$$V_{i'j',ij}^{AB} \equiv \langle \phi_{i'j'} | V^{AB} | \phi_{ij} \rangle = J_{AB} \langle a_{i'} | \sigma_N^x | a_i \rangle \langle b_{j'} | \sigma_{N+1}^x | b_j \rangle \quad (8)$$

factorizes into matrix elements of the local operators σ_N^x and σ_{N+1}^x in each block.

B. Hybridization ratio between two tensor-states

The level of hybridization between two tensor states ($ij \neq i'j'$) is determined by the ratio

$$R_{i'j',ij} \equiv \left| \frac{V_{i'j',ij}^{AB}}{\Delta E_{i'j',ij}} \right| \quad (9)$$

between the off-diagonal matrix element $V_{i'j',ij}^{AB}$ of Eq. 8 and the difference between the diagonal terms $\Delta E_{i'j',ij}$ of Eq. 7

$$\Delta E_{i'j',ij} \equiv \langle \phi_{i'j'} | H | \phi_{i'j'} \rangle - \langle \phi_{ij} | H | \phi_{ij} \rangle = (a_{i'} + b_{j'} + V_{i'j',i'j'}^{AB}) - (a_i + b_j + V_{ij,ij}^{AB}) \quad (10)$$

as follows : when the ratio is small $R_{i'j',ij} \ll 1$, the hybridization between the two tensor states ($ij \neq i'j'$) is small, when the ratio is large $R_{i'j',ij} \gg 1$, the hybridization between the two tensor states ($ij \neq i'j'$) is large.

C. Set of hybridization ratios for a given tensor-state

For a given tensor-state $|\phi_{i_0 j_0}\rangle \equiv |a_{i_0}\rangle \otimes |b_{j_0}\rangle$ one thus needs to consider the hybridization ratios $R_{i_0 j_0, ij}$ with all other tensor states $|\phi_{ij}\rangle$ in the Hilbert space of size $\mathcal{M} = M^2$. The question of the Many-Body-Localization is related to the statistics of these \mathcal{M} hybridization ratios $R_{i_0 j_0, ij}$ in the limit of large size $\mathcal{M} \rightarrow +\infty$. In this limit, it is convenient to decompose the hybridization ratios into two classes

$$\mathcal{M} = \mathcal{N}_{mixing}(\mathcal{M}) + \mathcal{N}_{nonmixing}(\mathcal{M}) \quad (11)$$

according to their behavior in the thermodynamic limit $\mathcal{M} \rightarrow +\infty$: $\mathcal{N}_{nonmixing}$ represents the number of hybridization ratios that converge towards zero $R \rightarrow 0$, while \mathcal{N}_{mixing} represents the number of hybridization ratios that do not converge to zero (they can diverge $R \rightarrow +\infty$ or remain finite $R = O(1)$).

In the Many-Body-Localized phase, where the entanglement between the two blocks satisfies the one-dimensional area-law and thus remains finite, an eigenstate $|\psi\rangle$ of the full Hamiltonian $H = H_A + H_B + V^{AB}$ can be well approximated by a Schmidt decomposition involving only a finite sum of tensor product states. This means that only a finite number of hybridization ratios $R_{i_0 j_0, ij}$ do not converge towards zero

$$\mathcal{N}_{mixing}^{Loc}(\mathcal{M} \rightarrow +\infty) \simeq O(1) \quad (12)$$

In the Many-Body-Delocalized phase, where the entanglement follows the volume law, an eigenstate $|\psi\rangle$ of $H = H_A + H_B + V^{AB}$ involves a diverging number of nearly equivalent terms in the Schmidt decomposition, i.e. a diverging number of tensor states $|\phi_{ij}\rangle$. This requires a diverging number of hybridization ratios that do not converge towards zero

$$\mathcal{N}_{mixing}^{Deloc}(\mathcal{M}) \simeq \mathcal{M}^\rho \quad (13)$$

with some exponent $\rho > 0$.

In summary, the behavior of the entanglement Schmidt decomposition of an eigenstate of $H = H_A + H_B + V^{AB}$ is directly related to the statistics of the hybridization ratios $R_{i_0 j_0, ij}$ of Eq. 9, and thus to the statistics of the matrix elements of local operators appearing in the off-diagonal matrix elements $V_{i_0 j_0, ij}^{AB}$ of Eq. 8. To analyze their statistics in the thermodynamic limit $\mathcal{M} \rightarrow +\infty$, it is convenient to use the multifractal formalism as described in the next section.

III. MULTIFRACTAL STATISTICS FOR MATRIX ELEMENTS OF LOCAL OPERATORS

A. Local magnetization as an example of local operator

For the block A containing N sites with an Hilbert space of size $M = 2^N$, the matrix elements of the magnetization σ_N^z

$$m_{nm} \equiv \langle a_n | \sigma_N^z | a_m \rangle \quad (14)$$

are of random sign. To characterize their modulus, it is thus convenient to introduce the corresponding Edwards-Anderson matrix

$$q_{nm}^{EA} \equiv | \langle a_n | \sigma_N^z | a_m \rangle |^2 = \langle a_n | \sigma_N^z | a_m \rangle \langle a_m | \sigma_N^z | a_n \rangle \quad (15)$$

that has the nice property to be doubly stochastic [58], i.e. it is a square matrix of size $M \times M$ of non-negative real numbers, where the sums over any row or any column is unity

$$\sum_{n=1}^M q_{nm}^{EA} = 1 = \sum_{m=1}^M q_{nm}^{EA} \quad (16)$$

as a consequence of the completeness identity

$$\sum_{n=1}^M |\phi_n\rangle \langle \phi_n| = \text{Id} \quad (17)$$

and the Pauli matrix identity $(\sigma_i^z)^2 = \text{Id}$. Doubly stochastic matrices appear very often in quantum mechanics (see for instance [7, 59, 60]). The normalization of Eq. 16 means that the $m = 1, 2, \dots, M$ values q_{nm}^{EA} can be interpreted as M random weights normalized to unity, so that the multifractal formalism is very appropriate to characterize their statistics as we now describe.

B. Multifractal exponents $\tau(q)$

After its introduction in fluid dynamics in order to characterize the statistical properties of turbulence (see the book [61] and references therein), the notion of multifractality has turned out to be relevant in many areas of physics (see for instance [62–68]), in particular at critical points of disordered models like Anderson localization transitions [69, 70] or in random classical spin models [71–79]. More recently, the wavefunctions of manybody quantum systems have been analyzed via multifractality for ground states in pure quantum spin models [80–93], as well as for excited states in MBL models [10, 94–96].

Here, we wish to analyze the statistics of the matrix elements $\langle \phi_n | \sigma_N^z | \phi_m \rangle$ where n is fixed and where $m = 1, 2, \dots, M$ goes over the whole Hilbert space of size $M = 2^N$ for the block A via the multifractal formalism as follows. The generalized moments $Y_q(M)$ define the multifractal exponents $\tau(q)$

$$Y_q(M) \equiv \sum_{m=1}^M |\langle \phi_n | \sigma_N^z | \phi_m \rangle|^{2q} \underset{M \rightarrow +\infty}{\propto} M^{-\tau(q)} \quad (18)$$

The related Rényi entropies involve the generalized fractal dimensions $D(q)$

$$S_q(M) \equiv \frac{\ln Y_q(M)}{1-q} \underset{M \rightarrow +\infty}{\propto} D(q) \ln M \quad (19)$$

with the simple relation

$$D(q) = \frac{\tau(q)}{q-1} \quad (20)$$

For $q = 1$, Eq. 19 corresponds to the standard Shannon entropy

$$S_1(M) \equiv - \sum_{m=1}^M |\langle \phi_n | \sigma_N^z | \phi_m \rangle|^2 \ln |\langle \phi_n | \sigma_N^z | \phi_m \rangle|^2 \underset{M \rightarrow +\infty}{\propto} D(1) \ln M \quad (21)$$

C. Multifractal spectrum $f(\alpha)$

Among the M eigenstates, the number $\mathcal{N}_M(\alpha)$ of eigenstates m that have with n a matrix element of order $|\langle \phi_n | \sigma_N^z | \phi_m \rangle|^2 \propto M^{-\alpha}$ defines the multifractal spectrum $f(\alpha)$

$$\mathcal{N}_M(\alpha) \underset{M \rightarrow \infty}{\propto} M^{f(\alpha)} \quad (22)$$

The saddle-point calculus in α of the moments of Eq. 18

$$Y_q(M) \simeq \int d\alpha M^{f(\alpha)} M^{-q\alpha} \propto M^{-\tau(q)} \quad (23)$$

yields

$$-\tau(q) = \max_{\alpha} (f(\alpha) - q\alpha) \quad (24)$$

i.e. $\tau(q)$ and $f(\alpha)$ are related via the Legendre transform

$$\begin{aligned} \tau(q) + f(\alpha) &= q\alpha \\ \tau'(q) &= \alpha \\ f'(\alpha) &= q \end{aligned} \quad (25)$$

D. Special values of q

1. Typical exponent α_0 for $q = 0$

For $q = 0$, Eq. 18 simply measures the size of the Hilbert space $Y_0(M) = M$ corresponding to $\tau(0) = -1$ and $D(0) = 1$ and to $f(\alpha_0) = 1$: this means that there exists an extensive number $O(M)$ of states having a matrix

element $|\langle \phi_n | \sigma_N^z | \phi_m \rangle|^2 \propto M^{-\alpha_0}$, so that

$$\alpha_0 = -\frac{1}{M} \frac{\sum_{m=1}^M \ln |\langle \phi_n | \sigma_N^z | \phi_m \rangle|^2}{\ln M} \equiv \alpha^{typ} \quad (26)$$

represents the typical exponent.

2. Shannon exponent α_1 for $q = 1$

For the Shannon value $q = 1$, the double stochasticity property corresponds to the normalization

$$Y_{q=1}(M) \equiv \sum_{m=1}^M |\langle \phi_n | \sigma_N^z | \phi_m \rangle|^2 = 1 \quad (27)$$

so that $\tau(q = 1) = 0$ and

$$\alpha_1 = f(\alpha_1) = D(1) \quad (28)$$

is called the 'information dimension' that characterizes the Shannon entropy of Eq. 21.

3. Smallest exponent $\alpha_{+\infty}$ for $q \rightarrow +\infty$

In the limit $q \rightarrow +\infty$, Eq. 18 is dominated by the configurations having the biggest possible matrix element $|\langle \phi_n | \sigma_N^z | \phi_m \rangle|_{max}$, and thus the smallest exponent $\alpha_{+\infty}$

$$\alpha_{+\infty} = -\frac{\ln |\langle \phi_n | \sigma_N^z | \phi_m \rangle|_{max}^2}{\ln M} = D(+\infty) \quad (29)$$

leading to $Y_{q \rightarrow +\infty} \simeq M^{-q\alpha_{+\infty}}$, since the corresponding singularity spectrum vanishes $f(\alpha_{+\infty}) = 0$. Note that here we consider the typical multifractal spectrum satisfying $f(\alpha) \geq 0$, that describes the statistics that are found in a typical sample (and not the average multifractal spectrum $f^{av}(\alpha)$ that keeps some meaning in the negative region $f^{av}(\alpha) < 0$ in order to describe events that happen in rare samples, see [70] for more details in the context of the Anderson transitions).

E. Simple examples of multifractal spectra

As a comparison, one should keep in mind that the monofractal spectrum corresponds to

$$\begin{aligned} f^{Mono}(\alpha) &= \delta(\alpha - 1) \\ \tau^{Mono}(q) &= (q - 1) \end{aligned} \quad (30)$$

1. Example of the Weak Multifractality Gaussian spectrum

The Weak Multifractality spectrum depending on the small parameter ϵ is a small deformation of the monofractal limit of Eq. 30

$$f^{Weak}(\alpha) = 1 - \frac{(\alpha - (1 + \epsilon))^2}{4\epsilon} \quad (31)$$

So it is Gaussian around the typical value $\alpha_0 = 1 + \epsilon$ and corresponds to the exponents

$$\tau^{Weak}(q) = (q - 1)(1 - \epsilon q) \quad (32)$$

This Weak Multifractality spectrum appears in particular at Anderson Localization Transition just above $d = 2$ [70].

2. Example of the Strong Multifractality linear spectrum

The Strong Multifractality linear spectrum

$$f^{Strong}(\alpha) = \frac{\alpha}{2} \quad \text{for } 0 \leq \alpha \leq 2 \quad (33)$$

corresponds to the exponents

$$\begin{aligned} \tau^{Strong}(q) &= (2q - 1) \quad \text{for } q \leq \frac{1}{2} \\ &= 0 \quad \text{for } q \geq \frac{1}{2} \end{aligned} \quad (34)$$

This Strong Multifractality spectrum appears in particular at Anderson Localization Transition in the limit of infinite dimension $d \rightarrow +\infty$ [70] or in related long-ranged power-law hoppings in one-dimension [97–111].

In the following, we will find that this Strong Multifractality Spectrum shows up again. The physical reason is that the MBL transition in one-dimension is somewhat similar to the Anderson Localization transition in the Hilbert space whose geometry is of 'infinite dimensionality' like trees, as a consequence of the exponential growth $M = 2^N$ of the size of the Hilbert space with the length N , as discussed in [47–52].

F. Matrix elements of local operators in the Delocalized phase

Let us first consider the case of completely random eigenfunctions in the Hilbert space, as in the Gaussian Random Matrix Ensemble. Then the matrix elements of the local magnetization display all the same scaling (only the numerical prefactor changes between diagonal and off-diagonal results [58])

$$| \langle \phi_n | \sigma_N^z | \phi_m \rangle |^2 \propto \frac{1}{M} \quad (35)$$

and correspond to the simple monofractal spectrum of Eq. 30

$$f^{GOE}(\alpha) = f^{mono}(\alpha) = \delta(\alpha - 1) \quad (36)$$

As recalled in the introduction, another possibility is that the delocalized phase is non-ergodic and described by some spectrum $f^{deloc}(\alpha)$ different from Eq. 36 (as found for Anderson localization on trees [51, 112] or as in some matrix model [53]). One general constraint is however that the minimal exponent has to be strictly positive

$$\alpha_{q=+\infty}^{deloc} > 0 \quad (37)$$

i.e. the matrix element of a local operator cannot remain finite in the delocalized phase.

G. Matrix elements of local operators in the Many-Body-Localized phase

For Many-Body-Localized eigenfunctions characterized by some finite localization length ξ , the matrix elements $| \langle \phi_n | \sigma_N^z | \phi_m \rangle |^2$ with a given state $|\phi_n\rangle$ are expected to be :

(i) finite and of order $2^{-\xi}$ for a finite number 2^ξ of other eigenstates m (i.e. each region of length ξ can be considered as ergodic within its reduce Hilbert space of size 2^ξ). In the multifractal language, this means that the multifractal spectrum begins at the origin

$$\alpha_{q=+\infty}^{loc} = 0 = f(\alpha_{q=+\infty}^{loc} = 0) \quad (38)$$

in contrast to Eq. 37 concerning the delocalized phase.

(ii) exponentially small in N for all other $(M - 2^\xi)$ eigenstates [56], i.e. they decay as a power-law with respect to the size $M = 2^N$ of the Hilbert space. To obtain a more precise description, one needs to know the number of eigenstates $M^{f^{loc}(\alpha)}$ that have a matrix element of order $| \langle \phi_n | \sigma_N^z | \phi_m \rangle |^2 \propto M^{-\alpha}$, i.e. one needs a multifractal description. Here it is important to stress the difference with the Anderson localization in finite dimension d , where the exponential localization decay $e^{-L/\xi}$ is not able to compete with the power-law behavior of the level spacing $\Delta E = 1/L^d$. This is why in Anderson localization models, the multifractality appears only at the critical point. Here on the contrary, the multifractal formalism is needed not only at criticality but also in the Many-Body-Localize phase.

IV. MULTIFRACTAL ANALYSIS OF THE HYBRIDIZATION RATIOS

A. Multifractal statistics of the coupling $V_{i_0 j_0, ij}^{AB}$

The coupling of Eq. 8 directly inherits the multifractal statistics of the matrix-elements $\langle a_{i_0} | \sigma_N^x | a_i \rangle$ and $\langle b_{j_0} | \sigma_{N+1}^x | b_j \rangle$ within each of the two blocks. Indeed the generalized moments read in terms of the size of the global Hilbert space $\mathcal{M} = M^2$

$$\begin{aligned} \sum_{i=1}^M \sum_{j=1}^M |V_{i_0 j_0, ij}^{AB}|^{2q} &= J_{AB}^{2q} \left(\sum_{i=1}^M | \langle a_{i'} | \sigma_N^x | a_i \rangle |^{2q} \right) \left(\sum_{j=1}^M | \langle b_{j'} | \sigma_{N+1}^x | b_j \rangle |^{2q} \right) \\ &\propto J_{AB}^{2q} M^{-\tau(q)} M^{-\tau(q)} = J_{AB}^{2q} \mathcal{M}^{-\tau(q)} \end{aligned} \quad (39)$$

So the number of tensor states (i, j) that have a coupling with the reference state (i_0, j_0) scaling as $|V_{i_0 j_0, ij}^{AB}| \sim \mathcal{M}^{-\alpha/2}$ is described by the same multifractal spectrum $f(\alpha)$ of Eq. 22

$$\mathcal{N}(|V_{i_0 j_0, ij}^{AB}| \sim \mathcal{M}^{-\alpha/2}) \propto \mathcal{M}^{f(\alpha)} \quad (40)$$

B. Hybridization Ratio between two consecutive energy levels

Following Ref. [56], let us first discuss the case of two consecutive levels separated by the level spacing

$$\Delta E_{i_0 j_0, next} = \frac{1}{\mathcal{M}} \quad (41)$$

The coupling between these two levels is governed by the typical exponent $\alpha_{q=0}$ (Eq. 26) in our present multifractal formalism

$$|V_{i_0 j_0, next}^{AB}| \sim \mathcal{M}^{-\alpha_0/2} \quad (42)$$

So the Hybridization ratio between two consecutive levels scales as

$$\frac{|V_{i_0 j_0, next}^{AB}|}{\Delta E_{i_0 j_0, next}} = \mathcal{M}^{1-\alpha_0/2} \quad (43)$$

This scaling is actually representative of all states having an energy difference scaling as $\Delta E_{i_0 j_0, i, j} \propto \frac{1}{\mathcal{M}}$. So the Many-Body-Localized phase can be stable only if Eq. 43 decays with the scale. This leads to the following bound for the typical exponent

$$\alpha_0^{loc} > 2 \quad (44)$$

Using $\mathcal{M} = M^2 = 2^{2N}$, the exponent κ characterizing the Many-Body-Localized phase in Ref. [56] corresponds to

$$\kappa = (\alpha_0^{loc} - 2) \ln 2 \quad (45)$$

in our present multifractal description.

In the Delocalized phase, the Hybridization ratio between two consecutive levels of Eq. 43 is expected to diverge, leading to

$$\alpha_0^{deloc} < 2 \quad (46)$$

In particular in the GOE monofractal case of Eq. 36 where

$$\alpha_0^{GOE} = 1 \quad (47)$$

the Ratio of Eq. 43 diverges as

$$R_{ab, next}^{GOE} = \mathcal{M}^{1/2} \quad (48)$$

C. Hybridization Ratio with the state having the biggest off-diagonal coupling

Another interesting special case is the state (i, j) having the biggest off-diagonal coupling with the state (i_0, j_0) , which is governed by the exponent $\alpha_{q=\infty}$ of Eq. 29 in our present multifractal formalism

$$V_{max} = \max_{(ij)} (|V_{i_0 j_0, ij}^{AB}|) \sim \mathcal{M}^{-\frac{\alpha_\infty}{2}} \quad (49)$$

The energy difference ΔE between these two levels is finite of order \mathcal{M}^0 , so that the Hybridization Ratio keeps the same behavior as Eq. 49

$$R = \frac{V_{max}}{\Delta E} \sim \mathcal{M}^{-\frac{\alpha_\infty}{2}} \quad (50)$$

In the Many-Body-Localized phase, this Hybridization Ratio with the maximally-coupled state is expected to be finite in agreement with Eq. 38

$$\alpha_{q=+\infty}^{loc} = 0 = f(\alpha_{q=+\infty}^{loc} = 0) \quad (51)$$

D. Multifractal statistics of the Hybridization Ratio $R_{i_0 j_0, ij}$

After the two extreme cases just described, let us now discuss the general case where the two levels are separated by \mathcal{M}^x intermediate levels with $0 \leq x \leq 1$. Taking into account the level spacing $\Delta E = \frac{1}{\mathcal{M}}$, the energy difference scales as

$$\Delta E_{i_0 j_0, ij} = \frac{\mathcal{M}^x}{\mathcal{M}} = \frac{1}{\mathcal{M}^{1-x}} \quad (52)$$

So the value $x = 0$ corresponds to the level-spacing scaling (Eq. 41), while the value $x = 1$ corresponds to finite energy difference.

With a numbering $n = 1, \dots, \mathcal{M}$ of energy levels, the change of variables $n = \mathcal{M}^x$ yields $dn = (\ln \mathcal{M}) \mathcal{M}^x dx$, i.e. at leading order without the logarithmic factor, the number of levels corresponding to a given exponent x is $\mathcal{M}^x dx$. From the multifractal statistics of the coupling $V_{i_0 j_0, ij} = \mathcal{M}^{-\alpha/2}$, one thus obtains that the number of Hybridization ratios $R_{i_0 j_0, ij} = V_{i_0 j_0, ij} / \Delta E_{i_0 j_0, ij}$ scaling as $R_{i_0 j_0, ij} \sim \mathcal{M}^{-\frac{\gamma}{2}}$ reads at the levels of exponential factors

$$\begin{aligned} \mathcal{N}(R_{i_0 j_0, ij} \sim \mathcal{M}^{-\frac{\gamma}{2}}) &\propto \int_0^{+\infty} d\alpha \mathcal{M}^{f(\alpha)-1} \int_0^1 dx \mathcal{M}^x \delta(\gamma - \alpha + 2(x-1)) \\ &\propto \int_0^{+\infty} d\alpha \mathcal{M}^{f(\alpha)-1} \int_0^1 dx \mathcal{M}^x \delta(x - (1 - \frac{\alpha - \gamma}{2})) \\ &\propto \mathcal{M}^{\frac{\gamma}{2}} \int_0^{+\infty} d\alpha \mathcal{M}^{f(\alpha) - \frac{\alpha}{2}} \theta(\gamma \leq \alpha \leq \gamma + 2) \equiv \mathcal{M}^{F(\gamma)} \end{aligned} \quad (53)$$

that defines the multifractal spectrum $F(\gamma)$ associated to the Hybridization Ratio for $-2 \leq \gamma \leq +\infty$.

E. Number \mathcal{N}_{mixing} of levels with a non-vanishing Hybridization Ratio

Using the notation of Eq. 11, one obtains that the number of hybridization ratios that do not converge towards zero corresponds to the region $-2 \leq \gamma \leq 0$

$$\begin{aligned} \mathcal{N}_{mixing}(\mathcal{M}) &= \int_{-2}^0 d\gamma \mathcal{N}(R \sim \mathcal{M}^{-\frac{\gamma}{2}}) \\ &\propto \int_{-2}^0 d\gamma \mathcal{M}^{\frac{\gamma}{2}} \int_0^{+\infty} d\alpha \mathcal{M}^{f(\alpha) - \frac{\alpha}{2}} \theta(\gamma \leq \alpha \leq \gamma + 2) \\ &\propto \int_0^2 d\alpha \mathcal{M}^{f(\alpha) - \frac{\alpha}{2}} \int_{-2+\alpha}^0 d\gamma \mathcal{M}^{\frac{\gamma}{2}} \end{aligned} \quad (54)$$

Since the last integral is dominated by the boundary $\gamma = 0$, one obtains

$$\mathcal{N}^{mixing} \simeq \int_0^2 d\alpha \mathcal{M}^{f(\alpha) - \frac{\alpha}{2}} = \mathcal{M}^{F(\gamma=0)} \quad (55)$$

in terms of the value $F(\gamma = 0)$ at $\gamma = 0$ of the multifractal spectrum of Eq. 53.

In Eq. 55, one has to do the same saddle-point calculation as in Eq. 23 for $q = 1/2$ except for the domain of integration, so it is important to discuss where the saddle point $\alpha_{q=1/2}$ is within the region $[0, 2]$.

F. Delocalized phase

In the Delocalized phase, using the bounds of Eqs 37 and 46, one obtains that the saddle point $\alpha_{q=1/2}$ lies in the integration interval of Eq. 55

$$0 < \alpha_{q=+\infty}^{deloc} \leq \alpha_{q=1/2}^{deloc} \leq \alpha_{q=0}^{deloc} < 2 \quad (56)$$

Then Eq. 23 yields using Eq. 20

$$\mathcal{N}_{mixing}^{deloc} \simeq \mathcal{M}^{f(\alpha_{q=1/2}) - \frac{\alpha_{q=1/2}}{2}} = \mathcal{M}^{-\tau(q=1/2)} = \mathcal{M}^{\frac{D(q=1/2)}{2}} \sim \mathcal{M}^{F^{deloc}(\gamma=0)} \quad (57)$$

i.e. the growth of the number of mixing levels is governed by the dimension $D^{deloc}(q = 1/2)$ corresponding to $q = 1/2$, and this dimension has thus to be positive in the delocalized phase (Eq 13)

$$F^{deloc}(\gamma = 0) = \frac{D^{deloc}(q = 1/2)}{2} = f^{deloc}(\alpha_{q=1/2}) - \frac{\alpha_{q=1/2}}{2} > 0 \quad (58)$$

The point $\alpha_{q=1/2} \in]0, 2[$ maximizing $(f(\alpha) - \frac{\alpha}{2})$ on the interval $0 < \alpha < 2$ satisfies the inequality

$$f^{deloc}(\alpha_{q=1/2}) > \frac{\alpha_{q=1/2}}{2} \quad (59)$$

For instance for the GOE case where $D^{GOE}(q = 1/2) = 1$ (Eq. 36), one obtains the scaling

$$\mathcal{N}_{mixing}^{GOE} \simeq \mathcal{M}^{\frac{1}{2}} = M \quad (60)$$

which coincides with the maximal number of terms in the Schmidt decomposition of an eigenstate. In addition, plugging the monofractal spectrum $f^{GOE}(\alpha) = \delta(\alpha - 1)$ into Eq. 53 yields

$$\mathcal{N}^{GOE}(R \sim \mathcal{M}^{-\frac{\gamma}{2}}) \equiv \mathcal{M}^{F^{GOE}(\gamma)} \propto \mathcal{M}^{\frac{\gamma+1}{2}} \theta(-1 \leq \gamma \leq 1) \quad (61)$$

so that the spectrum of hybridization ratios reads

$$F^{GOE}(\gamma) = \frac{\gamma+1}{2} \theta(-1 \leq \gamma \leq 1) \quad (62)$$

G. Many-Body-Localized phase

In the Many-Body-Localized phase, the number of mixing \mathcal{N}^{mixing} of Eq. 55 has to remain finite (Eq 12)

$$F^{loc}(\gamma = 0) = 0 \quad (63)$$

In addition, the saddle-point evaluation of Eq. 55 should be entirely due to the origin $\alpha = 0 = f^{loc}(0)$ (Eq. 38) as a consequence of the effective Hilbert space of size 2^ξ . This requirement that the saddle-point of Eq. 55 is at the origin means that

$$\alpha_{q=1/2}^{loc} = 0 \quad (64)$$

and that the multifractal spectrum for non-vanishing α satisfies the strict inequality

$$f^{loc}(\alpha) < \frac{\alpha}{2} \quad \text{for } 0 < \alpha \leq 2 \quad (65)$$

In particular this yields that on the interval $0 < \alpha \leq 2$, the multifractal spectrum remain strictly below the value unity $1 = f(\alpha_0)$ corresponding to the typical exponent α_0

$$f^{loc}(0 < \alpha \leq 2) < 1 = f^{loc}(\alpha_0) \quad (66)$$

i.e. one recovers that the typical exponent α_0 should satisfy the bound $\alpha_0^{loc} > 2$ of Eq. 44.

Taking into account the concavity property of the multifractal spectrum $f(\alpha)$ between the origin $\alpha = 0 = f(\alpha = 0)$ and the typical value $f(\alpha_0) = 1$ for $\alpha = \left(1 - \frac{\alpha}{\alpha_0}\right)0 + \frac{\alpha}{\alpha_0}\alpha_0$

$$f^{loc}(\alpha) \geq \left(1 - \frac{\alpha}{\alpha_0}\right)f(0) + \frac{\alpha}{\alpha_0}f(\alpha_0) = \frac{\alpha}{\alpha_0} \quad \text{for } 0 \leq \alpha \leq \alpha_0 \quad (67)$$

and the bound of Eq. 65, one obtains that near the transition when the typical exponent is close to $\alpha_0 = 2 + \epsilon$, there is no room left for curvature, and the multifractal spectrum is constrained to be linear of the form

$$f^{loc}(\alpha) \simeq \frac{\alpha}{\alpha_0} \quad \text{for } 0 \leq \alpha \leq \alpha_0 = 2 + \epsilon \quad (68)$$

Note that this linear spectrum for the Localized phase has already been found for the MBL case in [113] and for an Anderson Localization matrix model in [53].

Plugging the linear spectrum of Eq. 68 into Eq. 53 yields

$$\mathcal{N}^{loc}(R \sim \mathcal{M}^{-\frac{\gamma}{2}}) \equiv \mathcal{M}^{F^{loc}(\gamma)} \propto \mathcal{M}^{\frac{\gamma}{2}} \int_0^{+\infty} d\alpha \mathcal{M}^{\left(\frac{1}{\alpha_0} - \frac{1}{2}\right)\alpha} \theta(\gamma \leq \alpha \leq \gamma + 2) \theta(0 \leq \alpha \leq \alpha_0 = 2 + \epsilon) \quad (69)$$

Since $\alpha_0 > 2$, the integral in α is dominated by the smallest value of the integration interval, which is $\alpha_{min} = \gamma$ for $0 < \gamma < \alpha_0$, and which is $\alpha = 0$ for $-2 < \gamma < 0$, so that one obtains the following spectrum for the hybridization ratio R

$$\begin{aligned} F^{loc}(\gamma) &\simeq \frac{\gamma}{\alpha_0} \quad \text{for } 0 \leq \gamma \leq \alpha_0 = 2 + \epsilon \\ F^{loc}(\gamma) &\simeq \frac{\gamma}{2} \quad \text{for } -2 \leq \gamma \leq 0 \end{aligned} \quad (70)$$

Since the second lign corresponds to the negative region $F^{loc}(-2 \leq \gamma < 0) < 0$, it only represents rare events that do not occur in a typical sample, the typical multifractal spectrum is given by the first line alone, which remarkably coincides with the spectrum of matrix elements of Eq. 68.

H. Critical point

As the critical point is approached from the Many-Body-Localized phase $\epsilon = \alpha_0 - 2 \rightarrow 0^+$, the multifractal spectrum of Eq. 68 becomes

$$f^{criti}(\alpha) = \frac{\alpha}{2} \theta(0 \leq \alpha \leq 2) \quad (71)$$

that coincides with the known Strong Multifractality spectrum of Eq. 33 with the exponents

$$D^{criti}(q) = \frac{1 - 2q}{1 - q} \theta(q \leq \frac{1}{2}) \quad (72)$$

The vanishing dimensions for $q \geq 1/2$ and in particular for $q = 1/2$

$$D^{criti}(q = \frac{1}{2}) = 0 \quad (73)$$

matches the delocalized result of Eq. 57.

The difference with the Many-Body-Localized phase is that the integral of Eq. 55 for the number of mixing levels has now contributions from the whole interval $0 \leq \alpha \leq 2$ (instead of the concentration at the origin $\alpha = 0$), i.e. the resonances do not correspond only to finite matrix elements described by the value $\alpha = 0$, but involve all possible decays of matrix elements $|V^{AB}| \sim \mathcal{M}^{-\alpha/2}$ with $0 \leq \alpha \leq 2$.

For the hybridization Ratio, the multifractal spectrum of Eq. 53 reads at criticality

$$F^{criti}(\gamma) = \frac{\gamma}{2}\theta(-2 \leq \gamma \leq 2) \quad (74)$$

where the negative region $F^{criti}(\gamma) < 0$ for $\gamma < 0$ can only describe rare events that do not occur in a typical sample, while the positive region $F^{criti}(\gamma) \geq 0$ that describes what happens in a typical sample

$$F_{typ}^{criti}(\gamma) = \frac{\gamma}{2}\theta(0 \leq \gamma \leq 2) \quad (75)$$

coincides with the Strong Multifractal spectrum of Eq. 71.

I. Is a delocalized non-ergodic phase possible ?

As recalled in the Introduction, the existence of a delocalized non-ergodic phase remains very controversial. If it exists, it should be characterized by a multifractal spectrum intermediate between the critical spectrum of Eq. 71 and the monofractal GOE spectrum $f^{GOE}(\alpha) = \delta(\alpha-1)$. Above, we have obtained that in the Many-Body-Localized phase and at criticality, there are enough mathematical and physical requirements to determine the multifractal spectrum. In the Delocalized phase however, it is not clear to us presently if it is also possible to constraint the possible spectra.

However it is interesting to analyze the following family of linear spectra depending on the continuous parameter $\alpha_\infty \in [0, 1]$ obtained in an Anderson localization matrix model [53]

$$f_{\alpha_\infty}^{deloc}(\alpha) = \left(\frac{\alpha}{2} + \frac{\alpha_\infty}{2}\right)\theta(\alpha_\infty \leq \alpha \leq \alpha_0 = 2 - \alpha_\infty) \quad (76)$$

It can be considered as the simplest possible interpolation between the critical spectrum of Eq 71 for $\alpha_\infty = 0$ and the monofractal ergodic spectrum for $\alpha_\infty = 1$. The corresponding generalized dimensions read

$$\begin{aligned} D_{\alpha_\infty}^{deloc}(q) &= \frac{1 - q(2 - \alpha_\infty)}{1 - q} \quad \text{for } q \leq \frac{1}{2} \\ D_{\alpha_\infty}^{deloc}(q) &= \alpha_\infty \quad \text{for } q \geq \frac{1}{2} \end{aligned} \quad (77)$$

Note that the minimal exponent α_∞ describes all generalized dimensions $D_{\alpha_\infty}^{deloc}(q)$ for $q \geq 1/2$ and determines in particular the scaling of the number of mixing levels of Eq. 57

$$\mathcal{N}_{mixing}^{deloc} \propto \mathcal{M}^{\frac{D(q=1/2)}{2}} \sim \mathcal{M}^{\frac{\alpha_\infty}{2}} \quad (78)$$

Plugging Eq. 76 into Eq 53 yields

$$\begin{aligned} \mathcal{N}^{deloc}(R \sim \mathcal{M}^{-\frac{\gamma}{2}}) &\equiv \mathcal{M}^{F^{deloc}(\gamma)} \propto \mathcal{M}^{\frac{\gamma}{2} + \frac{\alpha_\infty}{2}} \int_0^{+\infty} d\alpha \theta(\gamma \leq \alpha \leq \gamma + 2)\theta(\alpha_\infty \leq \alpha \leq \alpha_0 = 2 - \alpha_\infty) \\ &\propto \mathcal{M}^{\frac{\gamma}{2} + \frac{\alpha_\infty}{2}} \theta(\alpha_\infty - 2 \leq \gamma \leq 2 - \alpha_\infty) \end{aligned} \quad (79)$$

so that the corresponding spectrum for the hybridization ratio

$$F^{deloc}(\gamma) = \left(\frac{\gamma}{2} + \frac{\alpha_\infty}{2}\right)\theta(\alpha_\infty - 2 \leq \gamma \leq 2 - \alpha_\infty) \quad (80)$$

interpolates between the critical result of Eq. 74 for $\alpha_\infty = 0$ and the GOE result of Eq. 62 for $\alpha_\infty = 1$. This spectrum is negative for $\gamma < -\alpha_\infty$, so the typical spectrum that describes what happens in a given sample corresponds to the region where the spectrum is positive

$$F_{typ}^{deloc}(\gamma) = \left(\frac{\gamma}{2} + \frac{\alpha_\infty}{2}\right)\theta(-\alpha_\infty \leq \gamma \leq 2 - \alpha_\infty) \quad (81)$$

In summary, if a delocalized non-ergodic phase exists, we feel that Eq. 76 is probably the best candidate. Further work is needed to determine whether it is indeed realized or whether it can be ruled out. From a numerical point of view, the simplest and clearest criterion should be the typical exponent $\alpha_0^{loc} > 2 = \alpha_0^{criti} > \alpha_0^{deloc}$: the ergodic phase corresponds to $\alpha_0^{ergo} = 1$, while a delocalized non-ergodic phase would correspond to

$$1 < \alpha_0^{nonergo} < 2 \quad (82)$$

So the question is whether the typical exponent displays a discontinuous jump from $\alpha_0^{criti} = 2$ to $\alpha_0^{ergo} = 1$, or whether it remains continuous with values in the whole interval of Eq. 82.

V. CONCLUSION

In this article, the local coupling between two long disordered quantum spin chains has been analyzed via the multifractal statistics of matrix elements of local operators in order to determine whether the interaction is able to reshuffle completely the eigenstates, as expected in the Delocalized phase with a volume-law entanglement, or whether the hybridization between tensor states remains limited, as expected in the Many-Body-Localized Phase with an area-law entanglement.

Our main conclusion is that for Many-Body-Localization models in one dimension with nearest-neighbors couplings, there are actually enough mathematical and physical requirements to determine completely the multifractal spectrum at criticality : it is found to be the Strong-Multifractality Spectrum $f(0 \leq \alpha \leq 2) = \frac{\alpha}{2}$. This result can be seen as the generalization to the whole spectrum of the criterion concerning only the typical exponent $\alpha_0^{typ} = 2$ proposed previously and tested numerically in Ref. [56] (see Eq 45 and the corresponding discussion). At the other end of the spectrum, the criterion concerning the minimal exponent $\alpha_{q=+\infty}^{loc} = 0$ (Eq. 38 and the corresponding discussion) can be related to the existence of an extensive number of emergent localized conserved operators in the Many-Body-Localized phase [33–41].

This Strong-Multifractality Spectrum is well-known in the context of Anderson Localization in spaces of effective infinite dimensionality, where the size of the Hilbert space grows exponentially with the volume. It should be stressed however that the observable displaying this multifractality is different in the two cases : in Anderson Localization models, the multifractality describes the inhomogeneities of the wave-function in real space and is measured by the Inverse-Participation-Ratios; in Many-Body-Localization models, the multifractality concerns the matrix elements between Hilbert space eigenstates of a local operator in real space. This shows one again that all the subtleties of the Many-Body-Localization problem are related to the understanding of what happens in the Hilbert space, what happens in real space and the interplay between the two. The fact that matrix elements of local operators are essential observables for the Many-Body-Localization transition is confirmed by their role in the Dyson Brownian approach [57, 58] where they govern the repulsion between energy levels. Physically, this Strong-Multifractality Spectrum represents the most inhomogeneous possibility within the multifractal point of view, and the corresponding critical statistics of energy levels is the closest possible to the Poisson statistics of the Localized phase, a possibility that has been studied via singular perturbation theory in [113], where the strong multifractality spectrum was also found to describe the entanglement spectrum at criticality. Note that this multifractal scenario for the Many-Body-Localization transition is very different from the current Renormalization Group proposals for the MBL critical point, which are based on the decomposition of the chain into insulating and thermalizing blocks of various sizes [42–44]. The multifractal picture is more similar to the standard description of the Anderson localization transitions, where the inhomogeneities at criticality are described by a multifractal spectrum and not by a black-and-white decomposition into localized and delocalized blocks.

Finally, we have discussed whether a delocalized non-ergodic phase could exist and proposed the numerical criterion of Eq. 82 to try to clarify this very controversial issue.
