## ABSTRACT

We exploited the high sensitivity of the INTEGRAL IBIS/ISGRI instrument to study the persistent hard X-ray emission of the soft gamma-ray repeater SGR 1900+14, based on  $\sim 11.6$  Ms of archival data. The 22–150 keV INTEGRAL spectrum can be well fitted by a power law with photon index  $1.9 \pm 0.3$  and flux  $F_x = (1.11 \pm 0.17) \times 10^{-11}$  erg cm<sup>-2</sup> s<sup>-1</sup> (20–100 keV). A comparison with the 20–100 keV flux measured in 1997 with *BeppoSAX*, and possibly associated with SGR 1900+14, shows a luminosity decrease by a factor of  $\sim 5$ . The slope of the power law above 20 keV is consistent within the uncertainties with that of SGR 1806–20, the other persistent soft gamma-ray repeater for which a hard X-ray emission extending up to 150 keV has been reported.

**Key words.** gamma rays: general – pulsars: individual: SGR 1900+14 – pulsars: general

## 1. Introduction

Soft gamma-ray repeaters (SGRs), together with anomalous X-ray pulsars (AXPs), are high energy sources which are thought to be magnetars, i.e. neutron stars whose emission is powered mainly by their strong magnetic field (see [Mereghetti et al. 2015](#) for a recent review).

Soft gamma-ray repeaters show recurrent short bursts (typical duration of the order of  $\approx 0.1$  s) in the X-ray and soft gamma-ray range, with peak luminosities of  $10^{39}$ – $10^{42}$  erg s<sup>-1</sup> for normal bursts and up to  $\approx 10^{47}$  erg s<sup>-1</sup> for giant flares. Bursts are usually emitted during active states that can last from a few days to months. Active states are interrupted by long quiescent (or non-bursting) time intervals with persistent luminosities of  $\approx 10^{33}$ – $10^{36}$  erg s<sup>-1</sup>.

In this paper we make use of the archival data of the International Gamma-Ray Astrophysics Laboratory (INTEGRAL, [Winkler et al. 2003](#)) collected in the period 2003–2013 to study the hard X-ray emission (above 20 keV) from SGR 1900+14.

Since the launch of INTEGRAL, SGR 1900+14 has shown only two periods of bursting activity: November 2002 ([Hurley et al. 2002](#)) and March 2006 ([Vetere et al. 2006](#); [Golenetskii et al. 2006](#)). Its persistent emission has been extensively studied, especially in the soft X-ray range ( $\lesssim 10$  keV) with *XMM-Newton* (e.g. [Mereghetti et al. 2006](#)), *Chandra* (e.g. [Göğüş et al. 2011](#)), *Suzaku* ([Nakagawa et al. 2009](#)), and *BeppoSAX* ([Tiengo et al. 2007](#); [Esposito et al. 2007](#)). The *XMM-Newton* and *Suzaku* spectra (0.8–10 keV) are well fitted either by an absorbed ( $N_H \approx 2.1 \times 10^{22}$  cm<sup>-2</sup>) power law ( $\Gamma \approx 1.9$  for *XMM-Newton*,  $\Gamma \approx 2.8$  for *Suzaku*) plus a black-body component ( $kT \approx 0.5$  keV) or by two absorbed black bodies ( $kT_1 \approx 0.5$  keV,  $kT_2 \approx 1.9$  keV;

[Mereghetti et al. 2006](#); [Nakagawa et al. 2009](#)). Persistent hard X-ray emission from SGR 1900+14 in the 20–100 keV has been discovered by [Götz et al. \(2006\)](#) using observations obtained with INTEGRAL in the period 2003–2004. The hard X-ray emission detected with INTEGRAL was fitted by a power law with photon index  $\Gamma \sim 3.1$ , significantly steeper than that of other SGRs and AXPs ([Götz et al. 2006](#)). [Esposito et al. \(2007\)](#) reported the detection of hard (20–150 keV) X-ray emission from a region around SGR 1900+14 with the non-imaging spectrometer Phoswich Detection System (PDS, [Frontera et al. 1997](#)) on board the *BeppoSAX* satellite. They modelled the observed X-ray emission with a power law with slope  $\Gamma \approx 1.6$ . Three transient X-ray sources were located within the PDS field of view, but none of them was in a bright state during the observation of SGR 1900+14. Therefore, the X-ray emission detected by *BeppoSAX* was likely produced by SGR 1900+14, although the contamination from other unknown transient sources within the PDS field of view cannot be ruled out ([Esposito et al. 2007](#)).

The hard X-ray emission of SGR 1900+14 has been studied so far with a limited set of data. In this work, we exploit  $\sim 10$  yr of archival INTEGRAL data to further investigate the properties of its emission above 20 keV, and put them in the broader context of the class of magnetars. In Sect. 2 we present the INTEGRAL observations on which our work is based, the data analysis procedure, and the results, which are discussed in Sect. 3.

## 2. Data analysis and results

We used data obtained with the INTEGRAL Soft Gamma-Ray Imager (ISGRI, [Lebrun et al. 2003](#)) detector of the coded-mask

**Fig. 1.** IBIS/ISGRI mosaic image (in  $\text{cts s}^{-1}$ ) of the SGR 1900+14 field in the 22–50 keV band.

telescope IBIS (Imager on board INTEGRAL Satellite, [Ubertini et al. 2003](#)). ISGRI operates in the  $\sim 15$ –400 keV band. IBIS has a fully coded field of view of  $9^\circ \times 9^\circ$  and a partially coded field of view of  $29^\circ \times 29^\circ$ .

We performed the reduction and analysis of IBIS/ISGRI data using the Off-line Science Analysis (OSA) 10.1 software provided by the ISDC Data Centre for Astrophysics ([Goldwurm et al. 2003](#); [Courvoisier et al. 2003](#)). We analysed all the public data between March 2003 and June 2013 where SGR 1900+14 was within  $12^\circ$  from the centre of the IBIS/ISGRI field of view. At larger off-axis angle the IBIS response is not well known<sup>1</sup>. We excluded all the data taken during bad time intervals. The resulting data set consists of 4706 pointings, corresponding to an exposure time of  $\sim 11.6$  Ms.

Sky images of each pointing were generated in the energy band 22–50 keV. SGR 1900+14 was never detected in the individual images because it was below the  $5\sigma$  threshold of detection.

We combined the individual images of the whole data set to produce the total (mosaic) image (see Fig. 1) in which SGR 1900+14 is detected with a significance of  $9.3\sigma$ . The pixel significance distribution of a sky image obtained from the convolution of the detector image<sup>2</sup> with a decoding array is expected to be Gaussian with zero mean and unitary standard deviation. Systematic errors that are not taken into account by the algorithm that reconstructs the sky image can lead to a broadening of this distribution ([Fenimore & Cannon 1978](#)). Systematic effects in the reconstructed image can be originated by the imperfect knowledge of the real instrument and can particularly affect observations of crowded regions of the Galaxy (e.g. [Krivonos et al. 2010](#)). We fitted the pixel significance distribution with a Gaussian with standard deviation of 1.18. Therefore, the significance of detection is reduced to  $9.3\sigma/1.18 \approx 7.9\sigma$  (for further details, see e.g. [Bélangier et al. 2006](#); [Li et al. 2011](#)).

<sup>1</sup> See the INTEGRAL data analysis documentation: <http://www.isdc.unige.ch/integral/analysis>

<sup>2</sup> The detector image is the shadowgram projected by the coded mask of the telescope on the detector plane.

**Notes.** Errors are at  $1\sigma$  confidence level.

## 2.1. Lightcurve analysis

We produced a lightcurve of SGR 1900+14 (Fig. 2) extracting the fluxes from nine mosaic images corresponding to the time intervals indicated in Table 1. Fitting these points with a constant, we obtain a reduced  $\chi^2 = 1.48$  (8 d.o.f.). Since this value has a large probability ( $\sim 16\%$ ) of being obtained by a constant source, we conclude that there is no evidence for variability in the INTEGRAL data. Note, however, that the large error bars of the measured hard X-ray count rates do not allow us to reveal relatively small flux variations, such as those measured for SGR 1900+14 at lower energy. In fact, variations of  $\sim 26\%$  in the soft X-ray flux (0.8–6.5 keV) were detected with *XMM-Newton* and *Chandra* during the period  $\sim 52\,700$ – $54\,520$  MJD that overlaps that of the INTEGRAL observations analysed in this work ([Göğüş et al. 2011](#)). Following [Primini et al. \(1993\)](#), we estimate that our observations could reveal at a  $3\sigma$  confidence level only flux variation larger than  $\sim 130\%$ .

## 2.2. Spectral analysis

We extracted the average spectrum of SGR 1900+14 using the source count rates obtained from the mosaic images in five energy bands (22–30, 30–38, 38–50, 50–70, 70–150 keV) using the OSA tool `mosaic_spec`, which is particularly suited

**Fig. 3.** Joint *XMM-Newton* (red), IBIS/ISGRI (black) spectrum fitted with an absorbed power law plus a blackbody model, with residuals in units of standard deviations.

for faint sources. We used the exposure-weighted average ancillary response file and the rebinned response matrix specifically generated for our particular data set. Before fitting, we added systematic uncertainties of 5% to the data set. We obtained a good fit ( $\chi^2_{\nu} = 0.5$ , 3 d.o.f.) with a power-law ( $\Gamma = 1.9 \pm 0.3$ ; uncertainties are at 90% c.l.) and 20–100 keV flux  $F_x = (1.11 \pm 0.17) \times 10^{-11}$  erg cm $^{-2}$  s $^{-1}$ .

Figure 3 shows the joint *XMM-Newton*, IBIS/ISGRI spectrum. We used the IBIS/ISGRI average spectrum obtained from the whole data set and the *XMM-Newton* data obtained on 2005 September 20 when the source was in quiescent state (Mereghetti et al. 2006). The analysis of EPIC-pn data was performed with the *XMM-Newton* Science analysis system (SAS) software, version 14.0.0. We rejected time intervals affected by high background, obtaining a total good exposure time of  $\approx 20$  ks. We included constant factors in the spectral fitting to allow for normalization uncertainties between the instruments and differences between the soft and hard X-ray spectra due to source variability and not simultaneous observations. We obtained an acceptable fit ( $\chi^2_{\nu} = 1.051$ ; 116 d.o.f.) of the joint *XMM-Newton*, IBIS/ISGRI spectrum with an absorbed ( $N_{\text{H}} = 2.5 \pm 0.2 \times 10^{22}$  cm $^{-2}$ ) blackbody ( $kT = 0.41 \pm 0.04$  keV) plus a power-law component ( $\Gamma = 1.87 \pm 0.17$ ). These parameters are consistent with those derived by Mereghetti et al. (2006) from the *XMM-Newton* data alone.

### 3. Discussion

We analysed 11.6 Ms of INTEGRAL data of SGR 1900+14, obtained from March 2003 to June 2013. We found that the 22–150 keV spectrum is well fitted by a power law with  $\Gamma = 1.9 \pm 0.3$  and flux  $(1.11 \pm 0.17) \times 10^{-11}$  erg cm $^{-2}$  s $^{-1}$ . A good agreement is found between the IBIS/ISGRI power-law photon-index and the soft value, measured below  $\sim 10$  keV with *XMM-Newton* during a quiescent state in 2005 (Mereghetti et al. 2006). The photon-index and significance of SGR 1900+14 presented here are significantly different from those obtained by Götz et al. (2006;  $\Gamma = 3.1 \pm 0.5$ , significance of  $9\sigma$ ) which were based on INTEGRAL data collected in the period March 2003–June 2004 (corresponding to Obs. number 1 of Table 1) and analysed with OSA 5.1. A comparison between the images obtained with OSA 10.1 and OSA 5.1 suggests that the discrepancy in the

results might be caused by the substantial improvement in the software that reconstructs the images of the sky from the shadowgram projected by the coded mask onto the detector plane. The images processed with OSA 5.1 showed spurious features, due to residual un-subtracted coding noise, caused by the brightest source in the field of view, GRS 1915+105, which contaminated the spectrum of SGR 1900+14. Such features are no longer present in the images reconstructed with OSA 10.1. Therefore, the spectral results reported here supersede those of Götz et al. (2006).

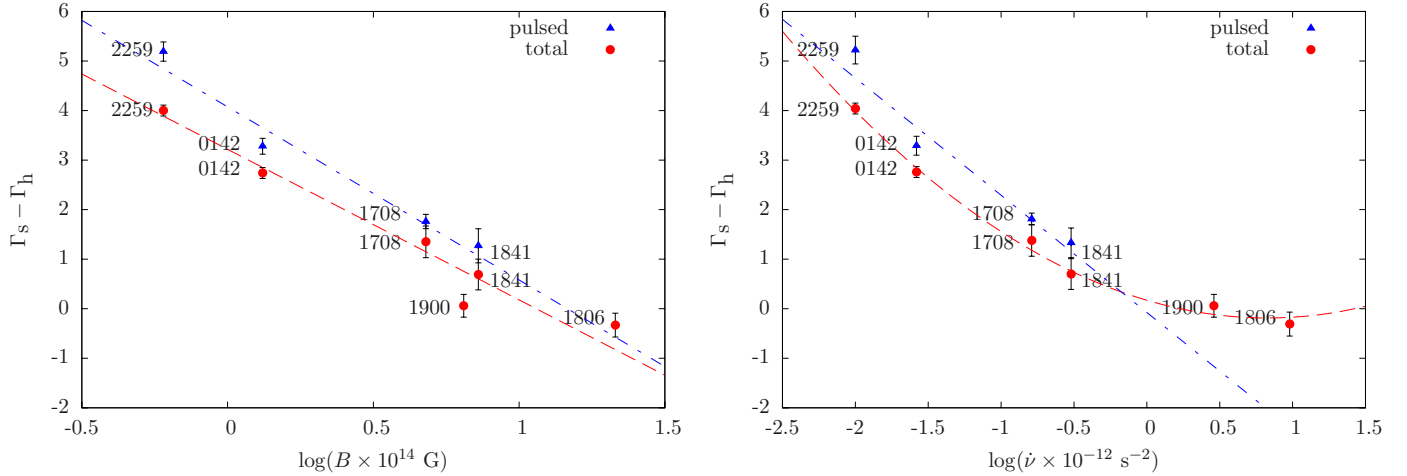

The slope of the hard X-ray spectrum derived with INTEGRAL is consistent with that measured with *BeppoSAX* before the giant flare of 1998, but the 20–100 keV luminosity ( $\approx 3 \times 10^{35}$  erg s $^{-1}$  for  $d = 15$  kpc, Vrba et al. 2000) is smaller by a factor of  $\sim 5$ . A similar decrease in the flux has been observed in the soft band, below  $\sim 10$  keV (Mereghetti et al. 2006; Göğüş et al. 2011).

Kaspi & Boydstun (2010) noted an anti-correlation of the spectral turnover  $\Gamma_s - \Gamma_h$  (where  $\Gamma_s$  is the photon-index in the soft band,  $\leq 10$  keV, and  $\Gamma_h$  is the photon-index in the hard band,  $\geq 10$  keV) with inferred magnetic field  $B$  and spin-down  $\dot{\nu}$ . These authors gave a qualitative interpretation for the anti-correlation  $\Gamma_s - \Gamma_h$  vs.  $B$  in the framework of models in which the X-ray emission of magnetars strongly depends on magnetospheric currents. For magnetars with higher  $B$ ,  $\Gamma_s$  is harder because the scattering optical depth between the relativistic electrons and the surface thermal photons increases. This in turn has an effect on the population of electrons that do not scatter and instead impact on the surface, heating it and creating a corona: fewer electrons will impact on the surface, resulting in a softer  $\Gamma_h$ .

Figure 4 shows an updated version of the plots  $\Gamma_s - \Gamma_h$  vs.  $B$  and  $\dot{\nu}$ . In addition to the magnetars considered by Kaspi & Boydstun (2010) and Vogel et al. (2014; 1E 2259+568, 4U 0142+61, 1RXS 1708–40, SGR 1900+14, 1E 1841–045, and SGR 1806–20), we included our new result for SGR 1900+14 and the pulsed flux of 1E 2259+568 from Vogel et al. (2014). To quantify the significance of the anticorrelation, we determined the Pearson’s linear coefficient  $r$  and the null hypothesis probability  $p$ . For the total flux data, we found  $r = -0.97$ ,  $p = 0.0012$  and  $r = -0.96$ ,  $p = 0.0025$ , for  $\Gamma_s - \Gamma_h$  as function of  $B$  and  $\dot{\nu}$ , respectively. For the pulsed data, we found  $r = -0.98$ ,  $p = 0.0157$  and  $r = -0.98$ ,  $p = 0.0236$  for  $\Gamma_s - \Gamma_h$  as function of  $B$  and  $\dot{\nu}$ , respectively. The new value of the spectral turnovers of SGR 1900+14 ( $0.06 \pm 0.23$  compared to the previous value  $-1.2 \pm 0.5$ ) and 1E 2259+568 (Vogel et al. 2014) improve the significance of the anticorrelation measured by Kaspi & Boydstun (2010). We used a linear model to fit the data ( $\Gamma_s - \Gamma_h = a + b \log_{10} x$ , where  $x = B$  or  $x = \dot{\nu}$ ). For  $\Gamma_s - \Gamma_h$  as function of  $B$  and total flux data set we found  $a = 46 \pm 2$ ,  $b = -3.04 \pm 0.14$ ,  $\chi^2 = 15.9$  (4 d.o.f.). For the pulsed flux we obtained  $a = 53 \pm 3$ ,  $b = -3.5 \pm 0.2$ ,  $\chi^2 = 9.2$  (2 d.o.f.). When considering  $\Gamma_s - \Gamma_h$  as function of  $\dot{\nu}$ , for total flux we found  $a = -17.4 \pm 0.9$ ,  $b = -1.51 \pm 0.07$ ,  $\chi^2 = 29.9$  (4 d.o.f.); for the pulsed flux:  $a = -29 \pm 3$ ,  $b = -2.4 \pm 0.2$ ,  $\chi^2 = 8.3$ , (2 d.o.f.). A quadratic model ( $\Gamma_s - \Gamma_h = a + b \log_{10} \dot{\nu} + c (\log_{10} \dot{\nu})^2$ ) fits better the total flux data:  $a = 65 \pm 15$ ,  $b = 12 \pm 2$ ,  $c = 0.5 \pm 0.1$ ,  $\chi^2 = 2.1$  (3 d.o.f.). Best-fit models are shown in Fig. 4.

### 4. Conclusions

We have reported on a new analysis of the hard X-ray emission from SGR 1900+14 based on ten years of observations with the IBIS/ISGRI instrument on the INTEGRAL satellite.

**Fig. 4.** Spectral turnover  $\Gamma_s - \Gamma_h$  as function of the magnetic field  $B$  (left panel) and spin-down  $\dot{\nu}$  (right panel) for all magnetars for which  $\Gamma_s$  and  $\Gamma_h$  are measured. Red circles represent total flux and blue triangles represent pulsed flux. Error bars represent  $1\sigma$  uncertainties. Linear fits are shown on the left panel, both for pulsed flux (blue line) and total flux (red line), and on the right panel for pulsed flux (blue line). For total flux data in the right panel, the best-fitting quadratic trend is shown. The figure is an updated version of Fig. 9 of Vogel et al. (2014), with the new value of  $\Gamma_s - \Gamma_h$  for SGR 1900+14 obtained in this work.

Thanks to the improved calibrations and analysis software, we obtained results that differ from and supersede those reported earlier for this source and based only on the first two years of data. We measured a 20–100 keV flux of  $F_x = (1.11 \pm 0.17) \times 10^{-11}$  erg cm $^{-2}$  s $^{-1}$ , which is lower than that seen in 1997 with *BeppoSAX* by a factor of  $\sim 5$ . While the previously found photon index at  $E > 20$  keV indicated a power law spectrum significantly softer than those of other SGRs and AXPs, the new value of  $1.9 \pm 0.3$  is similar to those found for the other sources and to that measured at lower energy for SGR 1900+14.
