(Received 13 June 2007; published 29 October 2007)

We use recently introduced three-point dynamic susceptibilities to obtain an experimental determination of the temperature evolution of the number of molecules N_{corr} that are dynamically correlated during the structural relaxation of supercooled liquids. We first discuss in detail the physical content of three-point functions that relate the sensitivity of the averaged two-time dynamics to external control parameters (such as temperature or density), as well as their connection to the more standard four-point dynamic susceptibility associated with dynamical heterogeneities. We then demonstrate that these functions can be experimentally determined with good precision. We gather available data to obtain the temperature dependence of N_{corr} for a large number of supercooled liquids over a wide range of relaxation time scales from the glass transition up to the onset of slow dynamics. We find that N_{corr} systematically grows when approaching the glass transition. It does so in a modest manner close to the glass transition, which is consistent with an activation-based picture of the dynamics in glassforming materials. For higher temperatures, there appears to be a regime where N_{corr} behaves as a power-law of the relaxation time. Finally, we find that the dynamic response to density, while being smaller than the dynamic response to temperature, behaves similarly, in agreement with theoretical expectations.

I. INTRODUCTION

One of the puzzling questions concerning the glass transition of liquids and polymers is the fact that the dramatic temperature dependence characterizing the slowing down of relaxation and viscous flow occurs with no significant variation of the typical structural length associated with static pair correlations (see, however, Ref. [1]). For instance, the static structure factor of a liquid barely changes from the high-temperature “ordinary” liquid down to the glass, while the main (α) relaxation time may rise by up to fifteen orders of magnitude. Yet, on intuitive ground, it is tempting to ascribe the strong temperature dependence of the dynamics and the ubiquity of the phenomenon, irrespective of molecular details, to a collective or cooperative behavior characterized by a length scale that grows as one approaches the glass transition. This is indeed the core of most theories of the glass transition [2,3], starting with the picture of “cooperatively rearranging regions” put forward by Adam and Gibbs in the mid-1960's [4].

From quite general arguments, one expects that a seemingly diverging, or at least long, time scale must be accompanied by a seemingly diverging, or at least large, length

scale [5]. Tracking such a length scale has been a long-standing goal of studies on glassforming materials. An exciting development in this direction has been the observation and description of the heterogeneous nature of the dynamics in viscous liquids and polymers [6–8]. Experiments carried out at temperatures near the glass transition and computer simulations on model liquids have shown that the dynamics of the molecules is indeed spatially correlated, with regions in space being characterized by mobilities or relaxation times substantially different from the average for a time scale at least equal to the main relaxation time. These dynamic heterogeneities come with (at least) one length scale that is typical of the correlations in space of the dynamics.

Measuring the length scale(s) associated with the spatial correlations of the dynamics is, however, a difficult task. Experimentally, the most direct measurements have been performed by means of solid-state multidimensional nuclear magnetic resonance, providing estimates of a few nanometers (between 5 and 10 molecular diameters) [6,7,9–11]. Unfortunately, these measurements can only be done in a narrow temperature range close to the glass transition, thereby precluding any study of the temperature dependence. Other types of dynamic length scales have been extracted from experimental data, mostly from crossover phenomena (e.g., between Fickian diffusion and non-Fickian translational motion [12]) or by some sort of dimensional analysis (e.g., from the product of a diffusion coefficient by a relaxation time or by the viscosity [13]; see also Ref. [14] and the discussion below).

*Permanent address: Laboratoire des Colloïdes, Verres et Nanomatériaux, UMR 5587, Université Montpellier II and CNRS, 34095 Montpellier, France.

Computer simulations give the opportunity to study the properties of the dynamic heterogeneities in more detail, with the restriction, however, that only the moderately viscous regime, many orders of magnitude away from the glass transition, is accessible. Sizes characteristic of one form or another of space-time correlations (strings [15], microstrings [16], compact “democratic” clusters [17], etc.) have been determined. On top of those studies, a more generic means of extracting a length scale associated with the dynamic heterogeneities, inspired by the mean-field theory of spin glasses [18], has been proposed and quite thoroughly investigated: the spontaneous fluctuations around the average dynamics give rise to a four-point time-dependent correlation function $\chi_4(t)$ called dynamic susceptibility [19]; its magnitude defines a “correlation volume” that follows a nonmonotonic variation with time t and displays a maximum for a time scale of the order of the α -relaxation time [20–24]. This correlation volume shows, in numerical simulations, a significant increase as temperature is decreased. At the present time, however, the dynamic susceptibility $\chi_4(t)$ cannot be experimentally measured in glassforming liquids and polymers, which prevents any overlap between simulations and experiments. This is because measuring $\chi_4(t)$ in principle amounts to resolving the dynamic behavior of molecules in both space and time, which has proven possible up to now only in systems such as colloidal suspensions [25,26], granular systems [27,28], and foams [29]. However, a promising path is to measure the nonlinear response of glassforming liquids, for example, their nonlinear dielectric constant, which contains information similar to $\chi_4(t)$ [30,31].

In spite of the progress made in the last decade, as briefly surveyed above, many important questions remain unanswered. To list a few: is there a unique length scale associated with the dynamic heterogeneities? Is the same length scale involved in the slowing down of the β and α relaxation? What is the temperature dependence of the dynamic length scale(s) over the whole range from the ordinary liquid phase to the glass? Is there a difference of behavior between the “strong” and the “fragile” glassformers? What kind of underlying static length, if any, may drive the growing dynamic length(s) in liquids and polymers?

The purpose of the present paper is not to answer, nor even to address, all of the above questions. We focus on the experimental determination of the temperature dependence of a length (more precisely, a volume or a typical number of molecules N_{corr}) that characterizes the space-time correlations in glassforming liquids. We do so by building upon the recent proposal made by some of us [32–34]. We study the experimentally accessible three-point time-dependent correlation functions defined as the response of a two-point time-dependent correlator to a change of an external control parameter, such as temperature, pressure, or density. In Ref. [32] it has been shown that the three-point correlation functions (that we will equivalently call “three-point dynamic susceptibilities”) can be used to provide a lower bound to the dynamic susceptibility $\chi_4(t)$. More recent work [33–35] has in fact established that these three-point susceptibilities contain *bona fide* information on the heterogeneous nature of the dynamics. In the present article, (i) we analyze dynamic data

on a variety of glassforming liquids to obtain three-point dynamic susceptibilities; (ii) we stress the arguments (and the conditions) that allow one to extract a number of dynamically correlated molecules $N_{\text{corr}}(t)$ (or a correlation volume); (iii) we study the temperature dependence of N_{corr} for a time scale of the order of the α -relaxation time τ_α and discuss its possible connection with the “fragility” (i.e., the degree of departure of τ_α from an Arrhenius temperature dependence) of the glassformers; (iv) we compare the relative contributions of temperature and density fluctuations to dynamical correlations; (v) finally, we discuss the connection between the extent of spatial dynamic correlations and some aspects of phenomenological descriptions of the glass transition, such as the degree of “cooperativity” of the relaxation processes and the nonexponential character of the relaxation functions.

II. EXPERIMENTAL ACCESS TO DYNAMIC SPATIAL CORRELATIONS

We have already mentioned that the natural quantity characterizing the spatial fluctuations of the dynamics, namely the dynamic susceptibility $\chi_4(t)$, has not so far been experimentally accessible in glassforming liquids. However, three-point correlation functions can be obtained as the response of a two-point correlator, commonly determined in experimental studies of the dynamics in glassformers, to a change in an external control parameter. Many aspects of the problem have been studied in great detail in Refs. [32–34]. Here, we mainly focus on the interpretation of the three-point dynamic susceptibilities and on the extraction from it of a length scale, or to the least of a volume or a number of molecules.

A. Preliminary: A phenomenological description

Consider a dynamic process that proceeds through thermal activation and is characterized by a typical time τ which follows an Arrhenius temperature dependence $\tau \propto \exp(\Delta/k_B T)$, where Δ is the activation energy barrier, k_B the Boltzmann’s constant, and T the temperature. An example is provided by the diffusion of vacancies in a solid. The activation barrier may be due to very local interactions, but in any case it is crossed because of energy fluctuations coming from the environment. A simple reasoning that allows one to derive a “correlation volume” associated with the activated dynamics is as follows. One just asks what is the volume V^* that is necessary to generate typical energy fluctuations of the order of the energy barrier Δ ? Typical energy fluctuations in a volume V are given by the square root of the variance of the total energy E in the NVT ensemble $\langle \delta E^2 \rangle_V = \rho k_B T^2 c_v V$, where c_v is the specific heat per particle in k_B units and ρ is the mean density. Equating Δ with $\sqrt{\langle \delta E^2 \rangle_V}$ gives immediately

$$\rho V^* = \frac{\Delta^2}{k_B T^2 c_v}. \quad (1)$$

If c_v does not vary much or even goes to zero as T goes to zero (as in a solid), then V^* increases at least as T^{-2} as temperature is lowered and ultimately diverges at $T=0$. This

result looks intriguing, but the “correlation volume” so defined appears more as the result of an exercise in dimensional analysis than motivated by describing spatial correlations in the dynamics. Actually, the nature of what *exactly* is *correlated in the volume* V^* is unclear (if not misleading).

Despite the obvious weakness of the approach, one may try to extend it to describe the slow, presumably thermally activated, dynamics in viscous liquids. There, however, the activation energy is not constant. The temperature dependence of the main (α) relaxation time τ_α is “super-Arrhenius” and one must choose an operational procedure to define an effective, temperature-dependent activation energy. One way is to define it through the relation $\tau_\alpha \propto \exp[\tilde{\Delta}(T)/k_B T]$, another possibility being to take the derivative of $\ln \tau_\alpha$ with respect to $1/T$, namely, $\Delta(T) = k_B \frac{\partial \ln(\tau_\alpha)}{\partial(1/T)}$. These two quantities are very different in fragile glassformers with a pronounced super-Arrhenius behavior, since $\Delta(T) = \tilde{\Delta}(T) - \partial \tilde{\Delta}(T) / \partial \ln T$. Anyhow, arbitrarily choosing at this stage the second definition and repeating the above argument leads to

$$\rho V^* = \frac{k_B}{c_v} \left(\frac{\partial \ln \tau_\alpha}{\partial \ln T} \right)_v^2, \quad (2)$$

which reduces to Eq. (1) when the dependence of τ_α is simply Arrhenius. This again results in a volume V^* or a number of molecules $N^* = \rho V^*$ which increases faster than T^{-2} as T decreases and approaches the glass transition. (This “correlation volume” is not to be confused with the “activation volume” sometimes introduced to characterize the pressure dependence of the α relaxation and defined as $T \partial \ln \tau_\alpha / \partial P|_T$.) A variant of the above reasoning was in fact proposed and further investigated by Donth [14,36], with the replacement of $(1/c_v)$ by $|\Delta(1/c_v)| \approx \Delta c_v / c_v^2$, where Δc_v is the jump in the heat capacity at the glass transition. In Donth’s interpretation, V^* (or N^*) is taken, with no justification, as the size of the “cooperatively rearranging regions” introduced by Adam and Gibbs [4].

The same line of reasoning can be followed in the NPT ensemble with the activation energy replaced by an activation enthalpy, leading to a correlation volume

$$\rho V^* = \frac{k_B}{c_p} \left(\frac{\partial \ln \tau_\alpha}{\partial \ln T} \right)_p^2. \quad (3)$$

It seems clear that for this approach to have any true physical meaning, it needs to be put on a much firmer basis and insight should be provided about the nature of the dynamic correlation. This is what we address below.

B. Multipoint dynamic correlation functions and susceptibilities

As was shown in Ref. [32] and further detailed in Refs. [33,34], multipoint space-time correlations in glassformers may be experimentally accessible by studying the response of the dynamics to a change in a control parameter, i.e., by inducing fluctuations in some conjugate quantity such as energy or density and monitoring its effect on the dynamics of the system. To provide a self-contained presentation, we briefly recall here the main arguments.

Standard experimental probes of the dynamics in liquids give access to the time-dependent autocorrelation function of the spontaneous fluctuations of some observable $O(t)$, $F(t) = \langle \delta O(0) \delta O(t) \rangle$, where $\delta O(t) = O(t) - \langle O \rangle$ represents the instantaneous value of the fluctuations of $O(t)$ from its ensemble average $\langle O \rangle$. One can think of $F(t)$ as being the average of a two-point quantity $C(0, t) = \delta O(0) \delta O(t)$ characterizing the dynamics. This quantity fluctuates around its mean value and information on the amplitude of those fluctuations is provided by the variance $\langle \delta C(0, t)^2 \rangle$, where $\delta C(0, t) = C(0, t) - F(t)$. This allows us to interpret $\chi_4(t)$ as a precise measure of dynamic fluctuations or heterogeneities, since $N \langle \delta C(0, t)^2 \rangle = \chi_4(t)$, where N is the total number of particles in the system. The associated spatial correlations show up more clearly when considering a “local” probe of the dynamics, such as, for instance, an orientational correlation function measured by dielectric or light scattering experiments, which can be expressed as

$$C(0, t) = \frac{1}{V} \int d^3 r c(\mathbf{r}; 0, t), \quad (4)$$

where V is the volume of the sample and $c(\mathbf{r}; 0, t)$ characterizes the dynamics between times 0 and t around point \mathbf{r} . For example, in the above mentioned case of orientational correlations, $c(\mathbf{r}; 0, t) \propto \frac{1}{N} \sum_{i,j=1}^N \delta(\mathbf{r} - \mathbf{r}_i) Y[\Omega_i(0)] Y[\Omega_j(t)]$, where Ω_i denotes the angles describing the orientation of molecule i , $\mathbf{r}_i(0)$ is the position of that molecule at time 0, and $Y(\Omega)$ is some appropriate rotation matrix element; the “locality” of the probe comes from the fact that it is dominated by the self-term involving the same molecule at times 0 and t or by the contribution coming from neighboring molecules.

The dynamic susceptibility can thus be rewritten as

$$\chi_4(t) = \rho \int d^3 r \langle \delta c(\mathbf{0}; 0, t) \delta c(\mathbf{r}; 0, t) \rangle, \quad (5)$$

where the statistical translational invariance of the liquid has been taken into account and $\rho = N/V$ denotes the mean density. The above equation shows that $\chi_4(t)$ measures the extent of spatial correlation between dynamical events between times 0 and t at different points of the system, i.e., the spatial extent of the dynamic heterogeneities over a time span t . Thanks to a number of recent theoretical and numerical studies [20–24], this point is now well documented.

Unfortunately, $\chi_4(t)$ has not so far been measurable in glassforming liquids and polymers. Furthermore, its physical interpretation is obscured by the fact that χ_4 turns out to depend strongly on microscopic dynamics and thermodynamical ensemble (see Refs. [33,34]). A related and experimentally feasible route to space-time correlations in glassformers consists in monitoring the response of the average dynamics to an infinitesimal change, say, of temperature. In the case of Newtonian dynamics, such as the molecules in a liquid, one can show that this response is given through a fluctuation-dissipation relation by a cross-correlation function involving the spontaneous fluctuations of the dynamics and those of the energy [32]. For simplicity, let us first focus on the NVT ensemble. In this case one finds [32]

$$\chi_T^{NVT}(t) = \left. \frac{\partial F(t)}{\partial T} \right|_{N,V} = \frac{N}{k_B T^2} \langle \delta E(0) \delta C(0, t) \rangle_{NVT}, \quad (6)$$

where $\delta E(0) = E(0) - \langle E \rangle$ is the fluctuation of the energy per molecule at time $t=0$. The subscript *NVT* means that the statistical average is performed in the *NVT* ensemble. Expressing the fluctuations in terms of local quantities (which is always possible [33,34,37]) as before leads to

$$\chi_T^{NVT}(t) = \frac{\rho}{k_B T^2} \int d^3r \langle \delta e(\mathbf{0}; 0) \delta c(\mathbf{r}; 0, t) \rangle_{NVT}, \quad (7)$$

where we have introduced $e(\mathbf{r}; t)$ as the energy density per molecule [hence, $NE(t) = \rho \int d^3r e(\mathbf{r}; t)$]. Note that the correlation functions in Eqs. (6) and (7) are expected to be negative since an increase in energy is likely to accelerate the dynamics, producing a negative change in $C(0, t)$.

The above equation shows that the three-point dynamic susceptibility $\chi_T(t)$, up to a factor $\rho/(k_B T^2)$, measures the spatial extent of the correlation between a fluctuation of energy at time 0 and at some point $\mathbf{0}$, and the change in the dynamics occurring at another point \mathbf{r} between times 0 and t . Clearly, $\chi_T(t)$ qualifies as a relevant quantitative indicator of space-time correlations in glassformers, whose temperature (or density) dependence is now experimentally accessible.

How does this alternative indicator relate to the dynamic susceptibility $\chi_4(t)$? On physical ground, it seems reasonable that energy fluctuations provide the main source of fluctuations in the dynamics, especially within a picture of slow activated relaxation with sizeable energy barriers (recall that we consider the *NVT* ensemble). As a result, spatial correlations between changes in the dynamics at different points can be mediated by the energy fluctuations, as thoroughly discussed in Ref. [33]. This view is supported by an exact relation that can be derived between $\chi_T(t)$ and $\chi_4(t)$ [32–34]. From the Cauchy-Schwarz inequality $\langle \delta E(0) \delta C(0, t) \rangle_{NVT}^2 \leq \langle \delta E(0)^2 \rangle_{NVT} \langle \delta C(0, t)^2 \rangle_{NVT}$ and the thermodynamic relation $N \langle \delta E(0)^2 \rangle_{NVT} = k_B T^2 c_v$, with c_v the constant volume specific heat per molecule in k_B units, one indeed obtains

$$\chi_4^{NVT}(t) \geq \frac{k_B T^2}{c_v} [\chi_T^{NVT}(t)]^2, \quad (8)$$

so that the experimentally accessible response $\chi_T(t)$ can be used to give a lower bound on the well-studied susceptibility $\chi_4(t)$. A rapidly growing energy-dynamics correlation as temperature decreases therefore directly implies a rapidly growing dynamics-dynamics correlation [33].

Actually, it can be shown that χ_4 and χ_T are more precisely related by

$$\chi_4^{NVT}(t) = \frac{k_B T^2}{c_v} [\chi_T^{NVT}(t)]^2 + \chi_4^{NVE}(t). \quad (9)$$

The dynamic susceptibility in the *NVE* ensemble $\chi_4^{NVE}(t)$ is a variance and therefore always positive, which of course is compatible with the inequality in Eq. (8). It is no more accessible to experimental measurements than $\chi_4^{NVT}(t)$, but it can nevertheless be computed in numerical simulations and in some theoretical approaches, as discussed in Refs. [33,34].

In particular, it was shown from simulations on two different models of glassforming liquids that for times of the order of τ_α (and in the range covered by the simulations) χ_4^{NVE} becomes small compared to $(k_B T^2/c_v)(\chi_T^{NVT})^2$ when temperature is low enough and the dynamics becomes truly sluggish, which then makes the lower bound in Eq. (8) a good estimate of χ_4^{NVT} . More importantly, the temperature dependences of χ_4^{NVE} and $|\chi_T^{NVT}|$ for $t \sim \tau_\alpha$ are found to be very similar, as can be proved exactly within the framework of the mode-coupling theory. Furthermore, for Brownian dynamics χ_4^B behaves as χ_4^{NVE} . These results strongly support the claim that the dynamic spatial correlations in glassforming liquids are in fact fundamentally contained in the three-point dynamic susceptibility χ_T (see Refs. [32–34] and the discussion in Sec. II E below). In this respect, it is satisfying that $\chi_T(t = \tau_\alpha)$ is found to be independent, for large τ_α , of the type of dynamics (Newtonian, Brownian, or Monte Carlo), as is the very phenomenon of glassy slowing down [38–41].

C. Experimental conditions: *NPT* thermodynamic ensemble

Most experimental situations in glassforming liquids and polymers correspond to the *NPT* ensemble. In order to carry out the analysis of the experimental data, one must first discuss the modifications brought about in the above presentation by switching the statistical ensemble from *NVT* to *NPT*.

The counterparts of Eqs. (6)–(9) are simply obtained by replacing energy by enthalpy and constant volume specific heat by constant pressure specific heat. For instance, one now has in place of Eq. (7)

$$\chi_T^{NPT}(t) = \frac{\rho}{k T^2} \int d^3r \langle \delta h(\mathbf{0}; 0) \delta c(\mathbf{r}; 0, t) \rangle_{NPT}, \quad (10)$$

where $\chi_T^{NPT}(t)$ is the derivative of $F(t)$ with respect to T when N and P are kept constant and where $h(\mathbf{r}, t)$ is the enthalpy density per molecule. Equation (9) is similarly changed into

$$\chi_4^{NPT} = \frac{k_B T^2}{c_p} (\chi_T^{NPT})^2 + \chi_4^{NPH}, \quad (11)$$

where the first term on the right-hand side is a lower bound for the nonlinear susceptibility χ_4^{NPT} and χ_T^{NPT} is, up to a factor $\rho/(k_B T^2)$, the integral of a correlation function between local fluctuations of the dynamics and of the enthalpy.

Under constant pressure conditions, a change in temperature is accompanied by a change in density. As a result, one can separate in the response of $F(t)$ to a change of temperature at constant pressure the effect of temperature at constant density, described by χ_T^{NVT} defined in Eq. (6), and the effect of density at constant temperature, characterized by $\chi_\rho^{NPT}(t) = \partial F(t)/\partial \rho|_T$. This allows us to generalize Eq. (11) to

$$\chi_4^{NPT} = \frac{k_B T^2}{c_v} (\chi_T^{NVT})^2 + \rho^3 k_B T \kappa_T (\chi_\rho^{NPT})^2 + \chi_4^{NVE}, \quad (12)$$

where κ_T is the isothermal compressibility of the liquid. The last term of the right-hand side being positive, one can now use the sum of the two first terms as a lower bound to χ_4^{NPT} , which is slightly different from that considered above, but

which explicitly takes into account all sources of fluctuations.

In any case, since both χ_T^{NVT} and χ_ρ^{NPT} can be experimentally obtained, the above expressions will allow us to evaluate the relative magnitudes of the contribution due to energy fluctuations and to density fluctuations in the space-time correlations, which represents an interesting issue *per se*.

D. From dynamic susceptibilities to correlation volumes

So far, we have presented a rigorous framework in which the spatially heterogeneous nature of the dynamics in glass-forming materials is described through susceptibilities that involve spatial correlations associated with the dynamics. One expects that those correlations die out at large separation, so that their integral over space provides a measure of the characteristic ‘‘correlation volume’’ at a given time t . It is then tempting, in light of Eqs. (5), (7), and (10), to interpret an increase with decreasing temperature of either $\chi_4(t)$ or $k_B T^2 |\chi_T(t)|$ (for t of the order of τ_α) as a signature of a dynamic correlation length scale or correlation volume that grow as the glass transition is approached.

Although the above considerations appear most plausible and indeed, as will be discussed below, are supported by a series of numerical and theoretical arguments, it is also worth stressing what could go wrong in the corresponding line of thought. With $\chi_4(t)$ and $\chi_T(t)$ one only has access to the integral over space of a correlation function, and two potential difficulties must be addressed. First, the correlation function should go to zero at large distances. Although this may sound as a trivial requirement, it is more subtle than anticipated and it depends on the statistical ensemble under consideration [33]. It is a well-known feature, even in the simplest case of the static pair correlation [37], that large distance limits of correlation functions in different ensembles differ by terms of the order $1/N$ or $1/V$. The difference is negligible in the thermodynamic limit, except when the function is integrated over the whole volume, as it is in susceptibilities [42]. It turns out that this is not an issue when all the conserved quantities are let free to fluctuate. For one-component molecular liquids, this corresponds to the *NPT* ensemble in which both energy and density may fluctuate; on the other hand, the (negative) asymptotic background contribution has to be taken into account in the *NVT* ensemble, which we will therefore no further consider.

Secondly, in the absence of more direct information on the spatial dependence of the correlation functions, extracting from their integral over space a ‘‘volume of correlation’’ (the derivation of a ‘‘correlation length’’ will be discussed below) requires an estimate of the amplitude of the correlation function to properly normalize the function. Indeed, an increase of χ_4 or $k_B T^2 |\chi_T|$ as T decreases could be due not only to the *extension in space* of the associated correlations, the phenomenon one is looking for, but also to a variation of the typical *amplitude* of the correlations. Disentangling the two effects is thus a prerequisite.

In the following, we focus on a time scale of the order of the α -relaxation time τ_α , for which the susceptibilities χ_4 and $|\chi_T|$ are found to reach a maximum. Relaxation on this time

scale, at least at low temperature, is known to be due to rare dynamic events associated with a significant apparent activation energy barrier (compared to $k_B T$). This implies that the relevant dynamical events typically affect $c(\mathbf{r}, 0, t \sim \tau_\alpha)$ on the order of a fraction of the mean value of the correlation function. Therefore, provided the function $C(0, t)$ is normalized by its mean value at $t=0$, $F(0) = \langle C(0, 0) \rangle$, which we shall assume from now on, such changes should be of order one and should not vary much with temperature.

The case of the dynamic susceptibility $\chi_4(t)$ is well documented. One expects that the typical magnitude of the auto-correlation function $\langle \delta c(\mathbf{0}; 0, t \sim \tau_\alpha) \delta c(\mathbf{r}; 0, t \sim \tau_\alpha) \rangle$ when \mathbf{r} is in the vicinity of point $\mathbf{0}$ is of order one when the dynamics is dominated by activated, intermittent processes. Hence $\chi_4(t \sim \tau_\alpha)$ is, up to a number of order unity, a measure of a correlation volume, or more properly [see the density factor in Eq. (5)] of a number of molecules that are dynamically correlated over a time span of the order of τ_α . More precisely, one can define

$$N_{\text{corr},4} = \max_t \{ \chi_4(t) \}, \quad (13)$$

the maximum occurring for $t \sim \tau_\alpha$.

Applying the same line of argument to the three-point susceptibility $\chi_T(t \sim \tau_\alpha)$ is a little more tricky because one now faces a cross-correlation function between enthalpy fluctuation at time 0 at a given point in space and fluctuation of the dynamics between $t=0$ and $t \sim \tau_\alpha$ in another place. First, the local enthalpy fluctuations that influence a dynamic event must have time to travel to the vicinity of the ‘‘active spot.’’ For instance, in the hydrodynamic limit, long-wavelength and small-amplitude enthalpy fluctuations follow a diffusive motion in a liquid, with a diffusion coefficient D_T ; the range of influence of such fluctuations must therefore be less than a length scale of the order of $\sqrt{D_T \tau_\alpha}$. However, because τ_α dramatically increases with decreasing T whereas D_T has a much weaker dependence, this hydrodynamic length scale is very large in viscous liquids and the upper bound it represents for dynamic correlations is of no real significance.

Secondly, the magnitude of the enthalpy fluctuations is temperature dependent, as shown by the thermodynamic relation $N \langle \delta H^2 \rangle = k_B T^2 c_p$. Removing this unwanted T dependence requires one to somehow normalize the variance of the enthalpy, e.g., to define a local dimensionless fluctuation of enthalpy density $\delta \hat{h}(\mathbf{r})$ via $N \delta H = \rho \sqrt{k_B T^2 c_p} \int d^3 r \delta \hat{h}(\mathbf{r})$. However, one may imagine that activated dynamic events associated with the α relaxation and leading to a change in δc of order one involve enthalpy fluctuations more sizeable than average, but *rare*. An appealing alternative is then to introduce another dimensionless enthalpy density fluctuation $\bar{\delta h}(\mathbf{r})$ through

$$N \delta H|_\alpha = \rho \sqrt{k_B T^2 \Delta c_p} \int d^3 r \bar{\delta h}(\mathbf{r}), \quad (14)$$

where Δc_p is the ‘‘configurational’’ part of the heat capacity of a glassforming liquid, i.e., that in excess of the associated glass: this describes the contribution of those enthalpy fluc-

tuations (indicated by the subscript α and whose typical size is given by $N\langle\delta H|_{\alpha}^2\rangle=k_B T^2\Delta c_p$) that precisely disappear when the α relaxation is frozen out on the experimental time scale. Presumably, the remaining fast components of the enthalpy fluctuations are then unable to induce the α relaxation, or at least are very weakly correlated with the α relaxation processes. (Nonetheless, and as usual, the temperature dependence of Δc_p can only be approximately determined experimentally by subtracting from the heat capacity of the liquid that of the crystal at the same temperature.)

Note that this distinction between typical and rare fluctuations is especially important in the presence of localized defects. Such defects, whose motion do not follow the standard hydrodynamic diffusion but is rather akin to that of “solitons” conserving their energy (or, at constant pressure, their enthalpy), have a negligible influence on the thermodynamics, hence on $c_p(T)$, provided they are dilute enough. In the case where such dilute defects are responsible for the slow relaxation of the system, it is clear that an estimate of the dynamic correlation volume based on characterizing the magnitude of the relevant enthalpy fluctuations by means of c_p would be meaningless, whereas Δc_p in this instance would precisely capture the defect contribution and lead to a reasonable estimate, see Ref. [34] for a discussion of defect models in this context. For glassforming liquids in general, the difference between c_p and Δc_p is not as dramatic, and in most cases remains of order of c_p itself [43].

From the above discussion, we conclude that an estimate of the number of molecules whose dynamics on the time scale of the α relaxation is correlated to a local enthalpy fluctuation is given by

$$N_{\text{corr},T} \sim \rho \left| \int d^3r \langle \delta \bar{h}(\mathbf{0};0) \delta c(\mathbf{r};0,t \sim \tau_{\alpha}) \rangle \right| \\ = \sqrt{\frac{k_B T^2}{\Delta c_p}} \max_t \{ |\chi_T(t)| \}, \quad (15)$$

where $\delta \bar{h}$ is the dimensionless fluctuation of energy density introduced above and where we have used the fact that $|\chi_T(t)|$ is maximum for $t \sim \tau_{\alpha}$ [33,34]. This is the central formula which bolsters our following analysis of experimental data in terms of number of dynamically correlated molecules.

E. Discussion

Before moving on to the actual analysis of experimental data, we would like to stress a number of points.

(i) $N_{\text{corr},4}$ versus $N_{\text{corr},T}$. *A priori*, $N_{\text{corr},4}$ and $N_{\text{corr},T}$ need not coincide, nor should they share the same temperature dependence. The former is the typical number of molecules whose dynamics are correlated “among themselves,” the latter the typical number of molecules whose dynamics are correlated “to a local fluctuation of enthalpy.” For Newtonian dynamics, and if the bound in Eq. (8) is nearly saturated, then these two numbers are actually quite different since

$$N_{\text{corr},4} \sim N_{\text{corr},T}^2. \quad (16)$$

This is indeed the result found within mode-coupling theory near its dynamic singularity [34]. This difference is, however, entirely due to the presence of one (or several) conserved variables. The primary mechanism creating dynamic correlations is captured by $N_{\text{corr},T}$ and is due to the fact that any local perturbation coupled to the slow dynamics (energy, density, composition, etc.) affects the dynamics over a certain volume, which grows as the glass transition is approached. This is measured by a certain dynamic response $\chi_d(|\mathbf{r}-\mathbf{r}'|,t)=\langle\partial c(\mathbf{r},t)/\partial e(\mathbf{r}',0)\rangle$ [33–35]. Now, summing over \mathbf{r} for a given point perturbation at \mathbf{r}' to define a correlation volume is identical to fixing \mathbf{r} but perturbing the system uniformly in space (while staying in a linear regime) [35]. This is the fundamental reason why χ_T , simply obtained by taking the derivative of C with respect to temperature, is related to a dynamical response. By the same token, the derivative of C with respect to any quantity coupled to dynamics is also a dynamic response; in the regime where these quantities become large, we expect that all of them ($\chi_T, \chi_{\rho}, \dots$) should behave similarly as a function of time and temperature, but with different prefactors (see Ref. [33] for a detailed proof of this point). We shall check this prediction on experimental data in Sec. V below.

Following the above reasoning, the difference between $N_{\text{corr},T}$ and $N_{\text{corr},4}$ comes from the fact that if energy is conserved, a local energy fluctuation at \mathbf{r} affects the dynamics in the surrounding, but also propagates in space to create another *correlated* dynamical fluctuation elsewhere. This, in effect, transforms $N_{\text{corr},T}$ into $N_{\text{corr},T}^2$. This justifies that we will mostly focus below on $N_{\text{corr},T}$ or $N_{\text{corr},\rho}$ and less on $N_{\text{corr},4}$. One should nevertheless keep in mind that some physical observables, such as the nonlinear (cubic) response to an external field, are directly related to $N_{\text{corr},4}$ [30], and that both three-point and four-point susceptibilities are deeply connected [32].

(ii) *Prefactors*. The uncertainty concerning the prefactors involved in extracting correlation volumes or numbers of correlated molecules, in particular the normalization problem discussed above, or the difference between using c_p and Δc_p , precludes a precise determination of the absolute value of those quantities. For instance, in the case of strong glassformers, the ratio $\Delta c_p/c_p$ may vary significantly, say from 1/2 to 1/10, between a fragile and a strong liquid. Choosing c_p or Δc_p , or even $c_p^2/\Delta c_p$ as proposed by Donth [36], then affects the relative estimates of the strong versus fragile glassformers. As found in Ref. [32], the order of magnitude of the resulting correlation volumes appears nonetheless physically sensible. Here, we shall focus on the variation with temperature which, as shown in the next section, is less sensitive to the estimate of the prefactors.

(iii) *Equation (3) recovered*. The simple phenomenological analysis described in Sec. II A is recovered by assuming that the shape of the relaxation function $F(t)$ in the α -relaxation regime does not vary with temperature, what is commonly referred to as “time-temperature superposition.” The only temperature dependence of $F(t)$ then comes through that of the relaxation time τ_{α} , $F(t,T)=\Phi[t/\tau_{\alpha}(T)]$

with $\Phi(0)=1$, which leads in the NPT ensemble to

$$N_{\text{corr},T} \sim \sqrt{\frac{k_B}{\Delta c_p}} \left| \Phi'(1) \frac{\partial \ln \tau_\alpha}{\partial \ln T} \right|, \quad (17)$$

where the prime on Φ indicates a derivative. By using now Eq. (16) and dropping the factor $|\Phi'(1)|$ that quantifies the stretching of the relaxation function and is thus of order one, one arrives at $N_{\text{corr},4} \sim \frac{k_B}{\Delta c_p} (\partial \ln \tau_\alpha / \partial \ln T)^2$, which is similar to Eq. (3).

The phenomenological derivation can thus be recast in a rigorous framework, which allows one to discuss the approximations made and, quite importantly, to understand the nature of the correlation that is probed. Essentially, the latter is the spatial correlation between local fluctuations of the dynamics and of the enthalpy. Any interpretation in terms of Adam-Gibbs-like cooperativity regions [14] requires additional, speculative steps that seem of dubious validity, as discussed further in Sec. VI.

(iv) *Link with numerical simulations.* A major advantage of having a rigorous formulation of the space-time correlations in liquids, relating dynamic susceptibilities to multipoint correlation functions, is that the heuristic considerations that we have developed in this and the previous subsections can be checked on models of glassforming liquids. Computer simulations are extremely useful in this context: one is guaranteed that the features of the dynamic heterogeneities that are probed in experiments are indeed the same as in simulations, except that the latter allow a much more detailed analysis, in particular concerning the full spatial dependence of the multipoint correlation functions, and not only their integral over space such as χ_T or χ_4 . The numerical investigations so far carried out unambiguously confirm the interpretation of Eqs. (15) and (16) for estimating the spatial extent of the correlations in the dynamics of glassforming liquids [33,34].

(v) *Length scales.* The growth of the number of correlated molecules $N_{\text{corr},T}$ as one lowers the temperature or, equivalently, of the associated correlation volume obtained by dividing $N_{\text{corr},T}$ by the density, is a strong indication of a growing correlation length. However, the precise relation is not straightforward. There is no reason indeed for the correlation volume(s) to be compact and therefore to scale as $N_{\text{corr}} \sim \xi^3$. Actually, if such a behavior were true for $N_{\text{corr},T}$, Eq. (16) would lead to $N_{\text{corr},4} \sim \xi^6$! Extracting a length scale is thus a highly nontrivial task which requires additional information on the spatial dependence of the multipoint correlation functions involved in $\chi_T(t)$ and $\chi_4(t)$. Again, such information is provided by numerical simulations and by model theoretical calculations (e.g., in the framework of the mode-coupling approach, where $N_{\text{corr},T} \sim \xi^4$ in the α regime, or in kinetically constrained models). The main result of both theoretical models and numerical simulations is that a *unique length scale* appears to characterize both $\chi_T(t)$ and $\chi_4(t)$, the associated correlation volumes being, however, noncompact [33–35].

III. DATA TREATMENT AND CALIBRATION

We have shown in the previous section that an estimate of the number of dynamically correlated molecules $N_{\text{corr},T}$ (and

via the lower bound $N_{\text{corr},4}$), can be obtained by measuring the sensitivity of two-time correlators to temperature changes, see Eq. (15). A standard tool to access such a two-time correlator in supercooled liquids is dielectric spectroscopy, and we have gathered published (and original) dielectric data on a range of glassforming liquids. In addition, in a few cases, we have also considered relaxation data obtained by other techniques, photon correlation spectroscopy, dynamic light scattering, optical Kerr effect, and neutron scattering. In this section, we review our operational protocol for treating the experimental data and we examine the uncertainties due to systematic or statistical errors. Readers interested only in the main physical results may skip this section and focus directly on the following ones.

A. Fitting the relaxation data

The quantity measured in dielectric spectroscopy is the linear susceptibility $\epsilon(\omega, T)$, which we have described at each available temperature by an efficient empirical parametrization, the Havriliak-Negami (HN) form [44] or the one proposed by Blochowicz *et al.* [45] on the basis of the extended generalized gamma function (GGE). The temperature dependence of the HN or GGE adjustable parameters have subsequently been fitted to a high-order polynomial or to a Vogel-Fulcher-Tammann form (the actual form of the function is not important as long as it fits well the data). From the HN or the GGE parametrizations, one can directly compute the associated relaxation function in the time domain [45] and then obtain the three-point dynamic susceptibility $\chi_T(t)$ by simply taking the derivative of the fitted temperature parametrization.

In the case of the other experimental probes that we have considered, the data is directly provided in the time domain. For light and neutron scattering, we have fitted the relaxation function to the standard Kohlrausch stretched exponential (KWW) function, whereas for the optical Kerr effect, we have used the parametrization given in Ref. [46]. As for the dielectric data, we have interpolated the temperature dependence of the parameters by polynomial or Vogel-Fulcher-Tammann functions and used the resulting formulas to compute the derivative with respect to temperature. In our operational protocol, we strictly limit ourselves to the domains of measurement, avoiding extrapolations as well as combinations of several sets of data.

B. Robustness of the temperature derivatives

Provided one does not extrapolate out of the experimentally accessed temperature domain, the above parametrization scheme provides a very good description of the temperature and time dependences of the measured relaxation functions. However, one must recall that we are ultimately interested in a derivative with respect to temperature of a quantity whose characteristic time scale varies by many orders of magnitude for small temperature changes. One must therefore study the robustness of the outcome.

As a first check, we have focused on the dielectric relaxation of glycerol. We have measured the linear dielectric susceptibility of glycerol every 1 K for a set of temperatures

FIG. 1. (Color online) Three different estimates (i)–(iii) detailed in Sec. III B for the full curve $T\partial\chi(\omega, T)/\partial T$ for glycerol at temperatures $T=196.6, 201.6, 207.1, 211.1, 217.2,$ and 225.6 K (from left to right). Full lines are for method (i), dashed lines for method (ii), and points for method (iii). The three methods give consistent results, with small deviations that are well understood.

above $T_g \approx 190$ K and below 232 K [47]. From the measured complex capacitance, $C(\omega, T)$, we have obtained the following normalized dynamical quantity:

$$\chi(\omega, T) = \frac{\epsilon'(\omega) - \epsilon_\infty}{\epsilon(0) - \epsilon_\infty} = \text{Re} \left[\frac{C(\omega) - C(\infty)}{C(0) - C(\infty)} \right], \quad (18)$$

where $\epsilon'(\omega)$ is the real part of the dielectric susceptibility. Contrary to $\epsilon(0)$, ϵ_∞ has not been directly measured and has instead been obtained from a fit of $C(\omega, T)$ using the HN parametrization. It turns out that $\epsilon_\infty/\epsilon(0)$ is a small number whose temperature dependence is sufficiently weak to be irrelevant in the calculation of the temperature derivative $\partial\chi(\omega, T)/\partial T$. We have computed the latter by three different methods. The first two are as described in Sec. III A: $\chi(\omega)$ has been fitted to (i) the HN and (ii) the GGE forms, and the temperature dependence of the parameters has been fitted as well; $\partial\chi(\omega, T)/\partial T$ has then been computed from the parametrization of the T and ω dependences. In procedure (ii), we have directly taken the parameter values given by Blochowicz *et al.* [45] from adjustment to their own dielectric measurements on glycerol. The third method (iii) consists of a direct calculation of $\partial\chi(\omega, T)/\partial T$ through finite differences on the experimentally measured capacitance: $\partial\chi(\omega, T)/\partial T \approx [\chi(\omega, T + \frac{\Delta T}{2}) - \chi(\omega, T - \frac{\Delta T}{2})]/\Delta T$, with ΔT a small, finite temperature step. Note that we have considered the frequency domain instead of the time domain because this allows a direct use of the raw data when computing the finite differences, without further manipulations.

The three different estimates obtained through (i)–(iii) are shown for several temperatures in Fig. 1. The results are very similar. At a given T , $\partial\chi(\omega, T)/\partial T$ reaches a maximum $\partial\chi/\partial T|_{\omega^*}$ at a frequency ω^* which is close to the frequency $\omega_\alpha \sim \tau_\alpha^{-1}$ at which the imaginary part $\epsilon''(\omega)$ of the dielectric susceptibility is maximum. The values ω^* and $\partial\chi/\partial T|_{\omega^*}$ are

very close for the three methods, with small differences which we now discuss.

The comparison of methods (i) and (iii) reveals that performing finite differences of raw data does not change the value of ω^* , but slightly underestimates the maximum $\partial\chi/\partial T|_{\omega^*}$ by an amount which increases with ΔT . For $\Delta T = 1$ K, the maximum value obtained through (iii) is lower than the two others by about 4%. The error on $\partial\chi(\omega, T)/\partial T$ due to our experimental uncertainties on the dielectric measurement is estimated to vary from less than 1% at the maximum $\partial\chi/\partial T|_{\omega^*}$ to 5% when $T\partial\chi(\omega, T)/\partial T$ is ten times smaller. In Fig. 1, it is worth noticing that method (iii) yields smooth curves despite the fact that no fitting procedure of the data is involved. This is consistent with error bars of at most 1% at the frequency ω^* .

As for the comparison between methods (i) and (ii) the difference between the values of $\partial\chi/\partial T|_{\omega^*}$ is small, less than 3%, as shown in Fig. 1. The main difference lies in the value of $\omega^*(T)$. Our values [following (i)] are smaller than those of Blochowicz *et al.* [45] by typically 20%. This amounts to decreasing all our temperature values by 0.6 K. Beyond a mere problem of thermometer calibration, this discrepancy may come from a difference in the purity of the glycerol samples, in particular their water content. It has been shown [48] that a glycerol sample protected from any humidity yields, at a given T , values of τ_α larger than those of a sample “regularly exposed” to air humidity, corresponding approximately to a temperature shift of 1 K, at least in the limited temperature interval considered here. This is quite larger than the difference reported in Fig. 1. To reinforce this interpretation, let us mention that in another series of experiments (not reported here) we have found values of $\omega^*(T)$ closer to those of Ref. [45]. The difference between our two sets of data amounts to a 0.17 K shift, while the exact same thermometer was used in both experiments. The important point for our present purpose is that the difference in $\omega^*(T)$ does not come with any significant difference in the maximum value of $\partial\chi/\partial T|_{\omega^*}$.

These detailed experiments performed on glycerol show that the temperature derivative involved in N_{corr} can be consistently obtained by using either finite differences (as also done in numerical work [33]), or a parametrization of the temperature and time (or frequency) dependences of the relaxation data through the HN or GGE descriptions.

C. Dependence of $N_{\text{corr}, T}$ on thermodynamic inputs

As discussed in Sec. II and illustrated by Eq. (15), determining $N_{\text{corr}, T}$ (and consequently $N_{\text{corr}, 4}$) requires thermodynamic input, primarily the isobaric specific heat c_p . For a few representative glassforming liquids for which enough data are available, we have investigated the two following points: (1) the quantitative difference in the estimate of $N_{\text{corr}, T}$ and its temperature dependence which is introduced by using either c_p or Δc_p , the value in excess to that of the associated crystal (see the discussion in Sec. II D); (2) the effect on the T -dependence of $N_{\text{corr}, T}$ that results from replacing $c_p(T)$ [or $\Delta c_p(T)$] by a constant value, taken at T_g , $c_p(T_g)$ [or $\Delta c_p(T_g)$]. There are indeed a number of glassforming materials for which only the latter value is known.

FIG. 2. (Color online) $N_{\text{corr},T}$ versus τ_α/τ_0 on a log-log plot for glycerol (top) and *o*-terphenyl (bottom). $N_{\text{corr},T}$ is calculated by using $c_p(T_g)$ (circles), $c_p(T)$ (squares), $\Delta c_p(T_g)$ (diamonds), and $\Delta c_p(T)$ (triangles). The two upper (lower) curves correspond to using Δc_p (c_p); τ_0 is arbitrarily set to 1 ps.

The results of our comparative study on two systems, glycerol [49] and *o*-terphenyl [50], are displayed in Fig. 2, where we plot $N_{\text{corr},T}$ as a function of τ_α/τ_0 , where τ_α is the α -relaxation time extracted from the HN fit of the dielectric data and τ_0 is an arbitrarily chosen microscopic time of 1 ps. One observes that the evolution is essentially the same in the different cases, using either $c_p(T)$, $\Delta c_p(T)$, $c_p(T_g)$, or $\Delta c_p(T_g)$. Replacing $\Delta c_p(T)$ by a constant $\Delta c_p(T_g)$ leads to a maximum deviation in $N_{\text{corr},T}(T)$ of about 10–15 % at high temperature around the melting point. Obviously, using Δc_p in place of c_p increases the absolute value of $N_{\text{corr},T}$, by up to a factor 2 in the case of *o*-terphenyl, but the whole shape of $N_{\text{corr},T}(T)$ is not significantly altered. Therefore, in what follows, we shall present results calculated with $\Delta c_p(T_g)$, or, when not available, with $c_p(T_g)$.

D. Dependence of $N_{\text{corr},T}$ on the experimental probe

In our estimates of $N_{\text{corr}}(T)$ we have focused on dielectric spectroscopy for which the largest data base is available. One may, however, inquire how much would the results change if other experimental probes were used. On the one hand, one

FIG. 3. (Color online) $N_{\text{corr},T}$ versus T_g/T for *m*-toluidine evaluated from dielectric (triangles) and photon correlation (circles) spectroscopies close to T_g , and by coherent quasielastic neutron scattering (squares) at high temperature. (We have not considered the two lowest temperature data points for which the determination of the relaxation profile is too uncertain.) The inset shows the corresponding relaxation times (determined from the maximum of the imaginary part of the dielectric susceptibility, from a KWW fit of the correlation functions obtained from photon correlation spectroscopy and neutron scattering at $q=1.3 \text{ \AA}^{-1}$).

expects that spatial correlations of the dynamics are an intrinsic property of the material, irrespective of the probe monitoring the dynamics. On the other hand, the estimates provided by Eqs. (15) and (16) are not as straightforward as one would like (see the discussion in Secs. II D and II E) and they may depend on the probe chosen. This can be simply illustrated in the case where the relaxation functions obey “time-temperature superposition.” As shown by Eq. (17), $N_{\text{corr},T}$ is proportional to $|\Phi'(1)|$, which is essentially the stretching parameter β [it is equal to β/e if $\Phi(x)$ is a stretched exponential e^{-x^β}]. If two probes are characterized by the same T dependence of their relaxation time but by different stretching parameters, which is not uncommon (see, e.g., Ref. [51]), the resulting estimates of $N_{\text{corr},T}$ then differ: the more stretched the relaxation (smaller β), the smaller the value of $N_{\text{corr},T}$.

Matter can be worse if time-temperature superposition does not hold. We illustrate this point by considering several sets of relaxation data for liquid *m*-toluidine: low-temperature (near T_g) dielectric [52] and photon correlation spectroscopy (PCS) [53] measurements, high-temperature (above and around melting) neutron scattering data. Over the limited domains of temperature studied, both dielectric [52] and neutron scattering relaxation functions appear to satisfy time-temperature superposition with (accidentally) almost the same stretching exponent $\beta \approx 0.6$ (the dielectric Kohlrausch stretching exponent is estimated from the fit in frequency domain according to [54]). On the other hand, the PCS data show a marked increase of the stretching, i.e., a decrease of β , as T_g is approached [53]. The resulting estimates of $N_{\text{corr},T}$ are shown in Fig. 3.

The PCS data lead to a smaller value of $N_{\text{corr},T}$ than the dielectric ones (by a factor of about 2) and to a slower

growth as one lowers the temperature near T_g . This behavior comes from the competition between the increase of $\log \tau_\alpha$ and the decrease of β as T decreases. Similar results could be expected for other molecular liquids due to analogous differences between dielectric and light-scattering dispersions [52,55].

The observation that average dynamic relaxations might depend on the probe is one of the puzzling experimental features of the glass transition. One usually gets away by arguing that τ_α from different probes are nevertheless consistent with one another, while different shapes result from different microscopic observables (when they can be properly defined). This becomes even more puzzling when these data are derived to obtain the value of $N_{\text{corr},T}$. If the observed averaged behaviors do not coincide, then it is no surprise that derivatives look even more different, as seen in Fig. 3. But this raises interesting questions if one wants to interpret the result in terms of a correlation volume: are there experimental probes that are “better” than others because more directly coupled to molecular degrees of freedom? Can the high precision obtained in the dielectric spectroscopy experiments of Sec. III B be obtained using other probes? Is the discrepancy observed in Fig. 3 due to the comparison of data with different resolutions? Can different microscopic observables be correlated over different length scales? Is it possible to extract a probe-independent correlation volume? More work is certainly needed to answer these questions.

IV. TEMPERATURE DEPENDENCE OF N_{corr} FOR A RANGE OF GLASSFORMERS

Having detailed how to estimate from experimental data the temperature dependence of the number of molecules whose dynamics are spatially correlated and discussed the robustness of our method, we now present the results for a variety of glassforming liquids. The data shown in Figs. 4 and 5 represent the central outcome of our work.

In Fig. 4 (top) we plot on a logarithmic scale $N_{\text{corr},T}$ determined using Eq. (15) versus τ_α/τ_0 , where τ_α is the α -relaxation time and τ_0 is a microscopic time arbitrarily fixed to 1 ps (except for a couple of systems discussed below). Due to the absence of data for Δc_p for the last three systems, results for all substances in Fig. 4 are computed using $c_p(T_g)$. The data include glycerol, *o*-terphenyl [52], *m*-toluidine [52], salol [56], propylene carbonate [45], *m*-fluoroaniline [45], propylene glycol [45], and decaline [57] (dielectric measurements), as well as B_2O_3 [58] (photon correlation spectroscopy), 2-biphenylmethanol (BPM) [46] and salol [59] (optical Kerr effect), and *m*-toluidine (neutron scattering). We have added for comparison simulation results obtained on two very different model glassformers, namely, the van Beest, Kramer, and Van Santen (BKS) model for silica [33] and a binary Lennard-Jones mixture [33]. In those two cases, the correlation functions used to probe the dynamics are self-intermediate scattering functions, and temperature derivatives are measured using finite differences of measurements performed at nearby temperatures T and $T + \delta T$, with δT small enough that linear response applies. For BKS silica, we take $\tau_0 = 1$ ps, while we take the standard Lennard-

FIG. 4. (Color online) Top: Evolution of $N_{\text{corr},T}$ for the different materials indicated when the glass transition is approached. The results are shown on a logarithmic scale as a function of τ_α/τ_0 , where τ_0 is a microscopic time scale (see the text). The full line is from Eq. (19) and describes a crossover from a power law scaling at high temperatures (small τ_α) to a logarithmic growth close to the glass transition, Eq. (19). Bottom: Using the freedom left by unknown normalizations of order unity we obtain a better collapse of the data onto the fit.

Jones time unit as a microscopic time scale, $\tau_0 = \sqrt{m\sigma^2/(48\epsilon)}$, where m , σ and ϵ , respectively, represent the mass of the particles, their diameter, and the depth of the Lennard-Jones potential; using argon units one gets $\tau_0 \approx 0.3$ ps. Finally, we have included a colloidal hard-sphere system, simply reporting the results already published in Ref. [32] and choosing $\tau_0 = 1$ ms.

A key feature in the results presented in Fig. 4 is that $N_{\text{corr},T}$ [and via Eq. (16), $N_{\text{corr},4}(T)$] does increase as temperature decreases or the relaxation time scale increases. The extent of spatial correlation in the dynamics therefore grows as one approaches the glass transition [32].

Although there is an unfortunate shortage of data covering the whole temperature range from above melting down to T_g , Fig. 4 clearly indicates that $N_{\text{corr},T}$ grows faster when τ_α is not very large. The initial, fast growth observed in N_{corr} occurs at high temperature, close to the onset of slow dynamics. A power law fit, $N_{\text{corr},T} \sim \tau_\alpha^{1/\gamma}$, in this regime (τ_α/τ_0

FIG. 5. (Color online) $N_{\text{corr},T}/N_{\text{corr},T}(T_g)$ (top) and τ_α/τ_0 (bottom) versus T_g/T for different glass-forming liquids (indicated in the figure) on a logarithmic scale; T_g is defined by $\tau_\alpha(T_g)=10$ s.

$< 10^6$) leads to values $\gamma=2-3$. Interestingly, these are consistent with the predictions of mode coupling theory, see Refs. [34,35]. The growth becomes much slower as T_g is approached. More quantitatively, if one wants to fit with a (second) power law in the regime $\tau_\alpha/\tau_0 \in [10^6, 10^{12}]$, one finds $N_{\text{corr},T} \sim \tau_\alpha^{1/\gamma'}$, with $\gamma' > 20$ and small variations among the different liquids. This means that when the dynamics slows down by 6 decades in time, $N_{\text{corr},T}$ merely increases by a factor about 2. This slow growth is actually broadly consistent with activation-based theoretical approaches which all predict some sort of logarithmically slow growth of dynamic length scales [60–63]. In order to capture the idea of a fast initial growth of $N_{\text{corr},T}$ when τ_α is small, followed by a logarithmically slow growth, we have empirically fitted the data to the formula

$$\tau_\alpha \simeq A \left(\frac{N_{\text{corr},T}}{N_0} \right)^\gamma \exp \left[\left(\frac{N_{\text{corr},T}}{N_0} \right)^\psi \right], \quad (19)$$

and found rough agreement (see the full line in Fig. 4) with $A=4$, $N_0=0.8$, $\gamma=2$, and $\psi=1.4$. (Note that very similar ideas

TABLE I. Values of $N_{\text{corr},T}(T_g)$ for various glassforming liquids, and corresponding lower bound on $N_{\text{corr},4}(T_g)$. The values are computed with $\Delta c_p(T_g)$. For completeness we report the values of c_p and Δc_p at T_g in $\text{J K}^{-1} \text{mol}^{-1}$.

Glassformer	$N_{\text{corr},T}(T_g)$	$N_{\text{corr},4}(T_g)$	Δc_p	c_p

propylene carbonate	15.9	252.8	75.4	164
<i>m</i> -fluoroaniline	12.9	166.4	86	161
propylene glycol	9.4	88.4	67.2	150
B_2O_3	10.1	102.0	40	131
<i>m</i> -toluidine	11.7	136.9	89.5	192.6
decaline	11.8	139.2	64	133

have been used in spin glass studies [64].) These values are unfortunately only indicative because a set of rather different values allows one to fit almost equally well the curves. It would be interesting to be able to narrow down the range of acceptable values for ψ in order to test more stringently the various activation-based theories found in the literature [60–63].

A second interesting feature of the results presented in Fig. 4 is that the data for different materials fall remarkably close to one another, despite the various caveats mentioned above about prefactors, normalization, etc., which might affect the vertical axis in this figure. A signature of such caveats is the fact that we find values of $N_{\text{corr},T}$ at high temperature which fall below 1. Investigating in detail the reasons of this behavior and improving the normalization procedure, however, would require the knowledge of the spatial distribution of the dynamical correlations, which is for the moment out of reach experimentally. Moreover our choice of a microscopic time scale (mainly 1 ps) is also somewhat arbitrary. Clearly, a better collapse of the different curves could be obtained by making use of the freedom offered by these unknown normalizations. In Fig. 4 (bottom) we rescale vertical and horizontal axis by factors of order unity (i.e., we only allow data shifts within a decade, very often much less) in order to obtain a better collapse along the fit described above. We find that all data collapse rather well, suggesting that Eq. (19) captures the physics of glassformers very well.

We show in Fig. 5 (top) the same data as in Fig. 4, normalized by the value of $N_{\text{corr},T}$ at T_g , versus T_g/T (excluding the simulation results and the colloidal system, for which T_g cannot be determined). Table I shows the different values of $N_{\text{corr},T}(T_g)$. Recall that estimates for $N_{\text{corr},4}(T)$ are simply obtained through Eq. (16), which on a logarithmic scale merely amounts to rescaling the y axis by a factor of 2.

In Fig. 5 we also compare the celebrated Angell plot (bottom) that illustrates the relative fragility of glassformers [65] to the relative change of $N_{\text{corr},T}(T)$ (top). We do not find any systematic correlation between the two plots, i.e., between the rapidity of the increase of $N_{\text{corr},T}(T)$ and the fragility (with the notable exception of decaline which is also the most fragile material considered). Indeed, the results for all

the systems show a rather similar behavior, characterized above all by a fairly modest growth of $N_{\text{corr},T}$. We note in passing that since Δc_p is taken here as constant and replaced by its value at T_g , Eq. (17) would on the contrary predict that $N_{\text{corr}}(T)$ follows the fragility pattern. The fact that this is not what is observed is mainly due to the breakdown of the time-temperature superposition property and the resulting effect of the shape (stretching) factor.

Finally, and keeping in mind the theoretical and practical uncertainties on the determination of the absolute value of N_{corr} , we note that the values of $N_{\text{corr},T}(T_g)$ for all studied glassformers are similar, all between 8.2 and 15.9 as shown in Table I. Contrary to what has been done in Ref. [32], we have not attempted here to convert this number into a precise length scale (see the discussion above), nor to “normalize” $N_{\text{corr},T}(T_g)$ [or $N_{\text{corr},4}(T_g) \approx N_{\text{corr},T}(T_g)^2$] by using an effective number of “beads” per molecule to account for the difference in complexity of the various molecules. The relative independence of $N_{\text{corr}}(T_g)$ upon fragility is broadly consistent with Wolynes’s version of the random first order theory [60,66], although the relation between N_{corr} and the typical size of the mosaic state is far from obvious—see the conclusion for a deeper discussion of this point.

V. RELATIVE EFFECTS OF TEMPERATURE AND DENSITY FLUCTUATIONS ON DYNAMICAL CORRELATIONS

The last question we want to address is the relative effects of temperature and density fluctuations on dynamical correlations. In Sec. II C, we have shown that the relative influence of temperature and density fluctuations on χ_4 is represented respectively by the contributions $k_B T^2 / c_v (\chi_T^{NVT})^2$ and $\rho^3 k_B T \kappa_T (\chi_p^{NPT})^2$. We have also argued in Sec. II E that both terms in fact represent a (squared) dynamic response and should behave similarly as a function of temperature, provided both T and ρ locally couple to the dynamics. It is therefore of interest to compare these two contributions, which we now do for three molecular liquids characterized by different fragilities: glycerol, *m*-toluidine, *o*-terphenyl.

We introduce a number of simplifications in our protocol. (1) We assume that the property of “time-temperature superposition” holds for the temperature range under study. This allows us to write the relaxation function as $F(t, T) = \Phi[t/\tau_\alpha(T)]$ with $\Phi(0)=1$ and no explicit T dependence elsewhere than in the relaxation time $\tau_\alpha(T)$. (2) We consider the thermodynamic coefficients c_p , c_v , κ_T , not the excess with respect to the crystal values, which usually are not all accessible. The data for $c_p(T)$ and the equation of state are taken from the literature [49,50,67–70] and c_v is obtained from the relation $c_v = c_p - \frac{T\alpha_p^2}{\rho\kappa_T}$, where α_p is the isobaric coefficient of expansion. (3) We use the scaling form onto which the density and the temperature dependences of the α -relaxation time and the viscosity of many glassforming liquids and polymers have been found to collapse [71,72]

$$\tau_\alpha(\rho, T) = f[e(\rho)/k_B T], \quad (20)$$

where $f(\cdot)$ is a species dependent, scaling function and $e(\rho)$ is a density-dependent (activation) energy scale. With the

above simplifications, and dropping the irreducible contribution coming from χ_4^{NVE} , one finds from Eq. (12):

$$N_{\text{corr},4}(\rho, T) \approx \Phi'(1)^2 \frac{k_B m_v^2}{c_v} (1 + \rho T \kappa_T c_v x^2), \quad (21)$$

where $m_v = -\partial \ln \tau_\alpha / \partial \ln T|_V$ is the “isochoric fragility,” which depends on ρ and T only through τ_α [71] and $x(\rho) = \partial \ln e(\rho) / \partial \ln \rho$ is found roughly constant over the range of densities involved at atmospheric pressure [71,72]. The ratio of the contribution of the density fluctuations over that of the energy fluctuations is then given by

$$R = \rho T \kappa_T c_v x^2. \quad (22)$$

As shown in the insets of Fig. 6, we find that R is roughly constant and close to 0.4 for glycerol, varies as T decreases from 0.7 to 0.6 for *m*-toluidine (note that in this case only values close to T_g are reported), and from 3 to 2 for *o*-terphenyl. These results are compatible with our expectation, detailed in Sec. II E, that density and temperature contributions mirror the same physical phenomenon, namely, the anomalous susceptibility of the dynamics to a local perturbation, and hence should share a similar temperature dependence. Thus, although the temperature contribution is dominant the other contribution behaves similarly as the temperature is lowered. In particular the ratio of the two terms changes modestly compared to their overall variation, except perhaps for *o*-terphenyl. It is known that in the latter case, density plays a more important role, as noticed for the slowing down of the relaxation [72]. It is, however, much less so in the other liquids where the contribution of the energy fluctuations dominate, especially at low temperature.

As a by-product of the present analysis, we can also evaluate the relative quality of the two lower bounds of χ_4^{NPT} that are provided either by Eq. (11) with χ_4^{NPH} neglected or Eq. (12) with χ_4^{NVE} neglected. The result for the three liquids already considered above is shown in Fig. 6. Because it takes more properly into account the relevant sources of dynamic fluctuations, the lower bound calculated with Eq. (12) is better than that obtained from Eq. (11). Although we do not have access to χ_4^{NPH} and χ_4^{NVE} individually, we can estimate their difference (evaluated as before for the time $t \sim \tau_\alpha$ at which χ_4^{NPT} is maximum). At T_g , we find that $(\chi_4^{NPH} - \chi_4^{NVE}) / (\chi_4^{NPT} - \chi_4^{NPH})$ is 0.15, 0.06, 0.31 for glycerol, *m*-toluidine, and *o*-terphenyl, respectively.

VI. CONCLUDING REMARKS

Our central result has been to provide direct evidence from experimental data for an increase of spatial correlations in the dynamics of glassforming liquids as one lowers the temperature [32]. Although the precise relation to a length scale is not straightforward (as discussed in Sec. II D), this nonetheless shows the existence of a length that grows as the glass transition is approached. Moreover, our results establish an important characteristic of this phenomenon: despite the dramatic slowing down of the relaxation in supercooled liquids, the growth of N_{corr} , and of the associated length

FIG. 6. (Color online) $N_{\text{corr},4}$ versus T_g/T for glycerol, *m*-toluidine, and *o*-terphenyl (top to bottom) calculated via the lower bounds given in Eqs. (11) (squares) and 12 (diamonds). Also displayed is the contribution due to energy fluctuations (circles). The inset shows the ratio R versus T_g/T [see Eq. (22)].

scale, is fairly modest, especially below the onset of slow dynamics. This is compatible with an activation-based picture of the dynamics in supercooled liquids. At higher temperature, however, the growth of this length scale appears to

be faster, and not inconsistent with the predictions of mode-coupling theory.

The modest size reached by the correlation volume at T_g also conveys a twofold message for future studies on the glass transition. (1) Experiments will presumably never be able to probe length scales as large as the ones measured for standard critical phenomena (where time and length scales are generically related in a power law fashion [73]). As a consequence, it is unlikely that the growing of the length scale may provide indisputable evidence that the slowing down is driven by an underlying phase transition, whatever its nature. Similarly, theoretical results that neglect subleading contributions to the asymptotic critical behavior will have to be taken with a grain of salt. (2) Despite the huge gap in time scales between experimental and numerical work, the probed length scales are not very different, which indicates the ability of numerical simulations to capture some major aspects of the slow dynamics in glassforming materials. A similar point was made in the context of spin-glasses [64,74].

We have already stressed in this article the direct connection between N_{corr} and the dynamic heterogeneities observed in glassforming systems: N_{corr} can be taken as the number of molecules participating in a typical dynamic heterogeneity. One may however wonder if N_{corr} and the associated length scale relate to other aspects of the slowing down of relaxation leading to the glass transition. Among these aspects are usually mentioned the “cooperative” nature of the α relaxation [2–4] and the stretching of the relaxation functions, often associated with a spread of local relaxation times [6–8].

A connection between N_{corr} and what is usually implied by “cooperativity” seems to us dubious, and certainly more work is needed to clarify this issue. Cooperativity, in the context of thermal activation, means that the effective activation energy is the sum of the elementary barriers associated with the motion of the objects that evolve cooperatively. In the Adam-Gibbs picture [4] these objects form a compact cluster, whereas in the frustration-limited domain picture [61] and presumably also in the random first order transition approach near the thermodynamic singularity T_K [60,63] these objects form (possibly fractal) domain walls. In all cases, however, the total effective activation energy is directly related to the number of correlated molecules, say N_{coop} , through

$$\Delta(T) = N_{\text{coop}}(T)^\theta \Delta_0, \quad (23)$$

where Δ_0 represents some elementary barrier that may or may not be temperature dependent, and θ is a certain exponent accounting for possible renormalization effects. As a result, $\tau_\alpha \propto \exp[N_{\text{coop}}^\theta \Delta_0 / (k_B T)]$. Now, using the above definition of $N_{\text{corr},T}$ in Eq. (15) and considering for illustration the simple picture in which $\theta=1$ and Δ_0 is independent of temperature (as in the traditional Adam-Gibbs approach), one obtains

$$N_{\text{corr},T} \sim \sqrt{\frac{k_B}{\Delta c_p}} \frac{\Delta_0}{k_B T} N_{\text{coop}} \left[1 + \frac{\partial \ln N_{\text{coop}}}{\partial \ln T} \right]. \quad (24)$$

Since Δc_p is weakly temperature dependent, this expression implies that N_{corr} [$N_{\text{corr},T}$ and, via Eq. (16) $N_{\text{corr},4}$ as well]

increases as temperature decreases even when N_{coop} is temperature independent (and equal to one, for that matter, which is tantamount to an absence of “cooperativity”). This discussion underlines that, contrary to the concept of “dynamic heterogeneity” that can be properly quantified, the notion of “cooperativity” in glassforming liquids lacks an operational definition that could then lead to concrete measurements of N_{coop} .

We also point out that no meaningful relation seems to emerge between $N_{\text{corr},T}$ and the stretching of the relaxation. Here, we do not refer to the way the stretching parameter enters in some expressions of $N_{\text{corr},T}$ and to the fairly unintuitive behavior that follows (see Sec. III D). We rather consider the common view of the stretching as a phenomenon which is attributed to the spatial heterogeneity of the dynamics (and initially triggered the whole body of work on dynamic heterogeneities) and which is connected to the “fragility” of the glassforming materials [75]. The main argument supporting the absence of link is the example of a simple system in which relaxation decays exponentially in time with a characteristic time that follows an Arrhenius temperature dependence. There is no stretching (and no “fragility”) and yet, $N_{\text{corr},T}$ increases as temperature decreases. It should be stressed again that our conclusions concerning $N_{\text{corr},T}$ apply to $N_{\text{corr},4}$ as well, since the two are intimately connected.

An additional illustration of the above points is provided in the case of the Fredrickson-Andersen (FA) models [76]. FA models can be seen as defect models, where stochastic rules for the dynamical evolution of the defects are postulated. In the simplest form of the model (the “one-spin facilitated FA model”), the relaxation of the system proceeds

by the thermally activated diffusion of point defects throughout the system. The average relaxation time in the system behaves in an Arrhenius manner, while two-time correlation functions decay exponentially, at least in three spatial dimensions. Such a local relaxation process can hardly be said to be “cooperative.” Yet, dynamics is very heterogeneous, in the sense that local dynamics is correlated on distances of the order of the typical distance between point defects, which can indeed become very large at low temperature. In this case, $\chi_4(t)$, χ_T , and N_{corr} all grow very strongly as temperature is decreased [24,77,78].

For all the above reasons, we conclude on a cautionary note: one should be careful in comparing numerical and experimental values of N_{corr} to theoretical predictions made by theories which do not directly investigate multipoint susceptibilities. This remark does not apply to mode-coupling theory and kinetically constrained models, but does apply to most activation-based theories, such as the Adam-Gibbs description [4], random-first order transition theory [60,63], or the frustration-limited domain approach [61].

ACKNOWLEDGMENTS

We thank T. Blochowicz for sharing the data analysis published in Ref. [45], R. Richert for the data in Ref. [52], and F. Zamponi for discussions.  [19] Originally, this four-point time-dependent correlation function was thought to be related to a dynamical susceptibility through the fluctuation-dissipation theorem [18]. However, it turned out that no such relation exists between the two quantities, correlation function and dynamical susceptibility, despite the fact that their behavior is similar in theoretical approaches such as the mode-coupling theory—see Ref. [34], Appendix A. For historical reason, the four-point function $\chi_4(t)$ is now commonly called dynamic susceptibility, although it does not directly represent a response of any kind. However, as shown in Ref. [30], the divergence, close to the glass transition, of the nonlinear (cubic) response to an external field reflects that of χ_4 .
