1. Introduction

The industrial revolution in Europe that mainly took place in the 19th century and the concomitant growth of urban activities led to major changes in land use. Many new factories created at that time produced high quantities of wastes (smelter slags, brick residues, coke or coal) which were extensively used as backfill materials for levelling purposes (Lehmann and Stahr, 2007; Testiati et al., 2013; Nehls et al., 2013). Since that time, these wastes – often contaminated with trace metals – became the parental material of soils which developed thanks to alteration mechanisms due to mechanical, geochemical and biological processes. The newly formed soils are generally called Technosols or Anthropic Soils (Rossiter, 2007; WRB, 2006) because they contain at least 20% of man-made materials within the first 100 cm of the profile. Although contaminated, these materials present a pedologic interest since they fulfill several functions such as biomass production, storage-filtration and transformation of nutriments, trace elements and water, or formation of ecological niches (Morel et al., 2015). Furthermore, they are now a central compartment for urban re-developers who try to build the city in the city to preserve agricultural soils (Reeve et al., 2012). Understanding their fate is then of primary importance.

Pedogenesis processes generally take place in a timescale of thousands of years (Minasny et al., 2008; Salvador-Blanes et al., 2007) and involve structural changes in the soil profile, including incorporation and transformation of organic matter as well as mineral dissolution and/or precipitation (Costantini et al., 2006; Duchaufour, 1976; Néel et al., 2003). Technosols are often contaminated (e.g. Tsolova et al., 2014; Wanat et al., 2013) and, by analogy with natural and cultivated soils (Huot et al., 2013), pedogenetic evolution will certainly influence the speciation, mobility and

46   bioavailability of pollutants they contain. However, the kinetics and mechanisms of

47   this evolution, as well as the consequences on pollutant speciation and mobility, are

48   poorly constrained. It is currently admitted that the pedogenic processes occurring in

49   Technosols are comparable to those occurring in natural soils, but can be accelerated

50   due to the large thermodynamic disequilibria that can exist between the media of

51   formation of the initial wastes and their new context of deposition (Séré et al., 2010;

52   Leguédois et al., 2016). Coherently, several studies showed that early pedological

53   transformations could be observed in Technosols, including oxidation,

54   decarbonatation, secondary minerals precipitation, roots colonization and even

55   humification in the first centimeters of the solum (Bataillard et al., 2008; Norra, 2006;

56   Séré et al., 2010), although the first industrial activities started in Europe at maximum

57   200 years ago.

58   Investigation of the kinetics and mechanisms of Technosols formation can be

59   performed by studying soil profiles where the deeper horizons are considered less

60   evolved than the upper horizons submitted to climatic and biologic alteration (Brahy et

61   al., 2000; Demattê and da Silva Terra, 2014; Egli et al., 2008). Hence, the deeper

62   horizons in a selected Technosol profile could be considered as the parent material of

63   the upper parts of the same profile. In this hypothesis, the characterization of the

64   surface and deep horizons gives valuable information about the evolution of the parent

65   material and the rates of alteration. However, because these materials have been

66   deposited by human activities, it may be pointed out that these horizons may also

67   differ due to their origin. This complicates the understanding of alteration impact on

68   the chemistry of Technosols: each observation and analytical result must be

69   interpreted with care.

70   In this study, the iron (Fe) status evolution is characterized during the early alteration

71   processes occurring in a 100-year old Technosol, and its consequences in terms of Zn

72   mobility are assessed. Fe, an ubiquitous element in natural and anthropic materials, is

73   of special interest because Fe minerals (i) are reported to be reliable and well-accepted

74   markers of soil evolution in soil sciences and (ii) control to a large extent the

75   distribution and mobility of trace metals in soils, especially in the absence of Mn

76   species (Bakker et al., 1996; Buol et al., 1973; Uzarowicz and Skiba, 2011). The slow

77   transformation of primary Fe-bearing silicates in oxic and well-drained conditions lead

78   to Fe depletion and precipitation of Fe (hydr)oxides such as goethite, lepidocrocite,

79   ferrihydrite or magnetite (Bakker et al., 1996; Tawornpruek et al., 2006). Formation of

80   free Fe (hydr)oxides can lead to the coating of soil particles with a thin film of these

81   Fe (hydr)oxides (Ben-Dor et al., 2006). These mechanisms can compete with Fe

82   complexation within the soil organic matter (Tipping et al., 2002).

83   For this study, a ~2m depth profile was sampled in a 100 years-old Technosol

84   developed on backfills that contain significant concentrations of metals (e.g. Zn).

85   Samples were characterized at different depths in order to quantify the changes in the

86   chemical status of Fe, to identify the main mechanisms responsible for the mobility of

87   trace elements such as Zn and to understand its consequences in terms of long-term

88   potential emission by the Technosol.

89

90   2. Material and Methods

91   2.1. Field site description

92   The present study was conducted at the "Union" former industrial site (Tourcoing, France),

93   located 50° 42' 35" N, 3° 9' 52" E. The site was occupied from the 19th century by several

94   types of industries, such as textile industries, breweries, smelters, chemical industries,

95   transport companies, and a gas plant (Figure 1). A rail yard was built at the end of the 19th

96   century at the north-west part of the site. Its reconversion for new activities is currently in

97   progress.

98   A parcel of about 1,500 m² was chosen at the northern part of the former rail yard (Figure 1).

99   The parcel shows a gentle slope from west to east, so that the railway (SW) is higher than the

100   road (NE). The parcel is free of any buildings.

101   A total of 5 pits were dug in the parcel and briefly investigated. Only one pit was held up and

102   kept for further investigation, whereas the remaining pits were filled up. Pit selection was

103   done according to the following criteria:

104   - Absence of material recently backfilled at the surface (e.g. recent natural earthy material was

105   found in some pits), and presence of aged backfills with evidences of vegetation development;

106   - Presence of a similar backfill material in depth which was not submitted to surface

107   alteration.

108

109   2.2 Technosol profile dating

110   Investigations were carried out at the archives of the SNCF (French railways) to assess the

111   probable date of setting of the backfills in the Technosol profile. A mail dating back October

112   6th, 1884 has indicated the establishment of a rail yard in the sector. Other archive documents

113   pointed out the construction of a railway in 1889, other earthworks in 1897 and the

114   construction of a special rail in 1898. Since then, no major works were done in the sector. The

115   study of aerial photographs taken between 1950 and 2015 proved that the frame of the rail

116 yard always remained similar to the one represented in a map dating back 1898 (see

117 supplementary material). Those photographs indicate also that the area where the Technosol is

118 located has never been built since then. Thus, the area of study was not reworked for a

119 century.

120

121   2.3.Technosol sampling and analyses

122 2.3.1. Soil profile sampling

123 The whole soil profile was sampled as a function of depth. Two types of samples were

124 collected: composite samples (~1 kg per sample) for bulk analyses and samples representative

125 of a given depth in the profile for punctual investigations (hereafter denominated "slices").

126 Composite samples were taken within the following range of depth: 0-10 cm (samples A), 30-

127 40 cm (samples C), 110-130 cm (samples E) and 175-185 cm (samples F). At each depth

128 range, three replicates were taken on a same horizon (Figure 2). The samples were kept as it is

129 in plastic bags and stored at 4 °C before analyses.

130 Soil slices were taken at 5 cm (LM1), 90 cm (LM2) and 180 cm (LM3) deep. The soil

131 structure was preserved (non-destructive sampling using cylinders) and 3 thin sections

132 embedded with epoxy resin were elaborated (final thickness: 30 μm).

133

134 2.3.2. Bulk analyses

135 In laboratory, after measuring the water content of the composite samples, the soil pH was

136 measured in a 1:5 (volume fraction) suspension of soil in deionized water according to NF

137 ISO 10390. The total organic carbon content (TOC) was determined by dry combustion

138 analysis according to NF ISO 10694. Organic carbon was analyzed after removal of

139 carbonates by acidification using hydrochloric acid. Grain size distribution and total elemental

140 concentrations were determined according to standardized methods (AFNOR, 1996, NF X

141 31–147). Cation exchange capacity (CEC) and exchangeable cations were measured with the

142 cobaltihexamine chloride method (Orsini and Rémy, 1976), which can safely be used here, as

143 samples contain little or no Fe(II)-bearing minerals (Hadi et al., 2016).

144

145 2.3.3 Leaching tests and selective dissolution

146 The release of trace elements was assessed by leaching of the composite samples. The 3

147 replicate samples taken at each depth range were tested. The samples were air dried and

148 sieved (cut-off diameter of 2 mm). Then, the leaching tests were conducted at room

149 temperature (20°C±2°C), in closed PTFE reactors with continuous stirring during 24h. A

150 liquid/solid ratio of 10 was used with deionized water, corresponding to 10 g of dry sample in

151 100 mL water. The leachates were then filtrated (cut-off diameter of 0.45 µm) and analyzed

152 by ICP-AES (major and trace elements such as Zn).

153 The Fe status was assessed by selective dissolution, using both Dithionite-Citrate-Bicarbonate

154 (DCB) and pyrophosphate methods, done in parallel on aliquots. The methods used are

155 detailed in Table 1. DCB selectively solubilizes pedogenic oxides and hydroxides (Mehra and

156 Jackson, 1960). This method can solubilize crystalline Fe (hydr)oxides (hematite, goethite),

157 non-crystalline Fe (hydr)oxides and Fe and Al organic complexes, whereas magnetite is

158 slightly attacked and clays are unaffected. The pyrophosphate method was used to dissolve

159 amorphous Fe(III), Fe(II) complexes and/or very poorly crystalline compounds (Pansu and

160 Gautheyrou, 2006). Well-crystallized Fe (hydr)oxides like goethite and hematite are not

161 attacked and slightly ordered Fe (hydr)oxides are only slightly solubilized. Claff et al. (2010)

162 tested the effect of these sequential chemical extractions on synthetic Fe minerals

163 representative of some of those most abundant in the environment (e.g., akaganeite,

164 ferrihydrite, goethite, hematite, jarosite, magnetite, pyrite and schwertmannite). They

165 demonstrated that sodium pyrophosphate does not dissolve any of the tested minerals. The

166 DCB procedure dissolves totally or significantly akaganeite, magnetite, goethite, hematite and

167 ferrihydrite, and to a minor extent, jarosite.

168

169 2.3.4 Powder X-Ray diffraction analysis (XRD) on composite samples

170 The mineralogical assemblage of each composite sample was assessed by XRD, using a

171 Siemens D5000 diffractometer with cobalt X-ray tube (CoKα radiation). The powdered

172 composite samples were scanned with steps of $0.03°2\theta$ and a counting time of 10s per step, in

173 the $4\text{-}84°2\theta$ angular range. Mineral identification and semi-quantitative determination of

174 relative abundances of crystalline phases was performed using the software DIFFRAC plus

175 EVA.

176 XRD patterns of composite samples were subjected to quantitative mineralogical analysis

177 using the SIROQUANT[TM] software. The quantification is based on the principles of Rietveld

178 refinement (Rietveld, 1969). In addition to crystalline phases, SIROQUANT[TM] was used to

179 indirectly determine the amorphous phase content by spiking the samples with corundum

180 internal standard. A precisely evaluated proportion of corundum by weight (target value of

181 10%) was added to the samples. The amorphous content was calculated by a routine within

182 the SIROQUANT[TM] program using a correction based on the weight-in proportion in the

183 spike added prior to the XRD analysis.

184

185   2.3.5 Fe and Zn X ray absorption spectroscopy (XAS) analysis on composite samples

186   To complement selective dissolution for the study of Fe status, XAS analyses were carried out

187   on composite samples. Moreover, the status of Zn, a recurrent trace element occurring in this

188   Technosol, was also studied by XAS. The experiments were carried out at the Pacific

189   Northwest Consortium Synchrotron Radiation Facility (PNCSRF) bending magnet beamline

190   of the Advanced Photon Source (Argonne, IL, USA). The XAS spectra of composite samples

191   were recorded, as well as those of reference minerals: natural hematite, natural 6L

192   ferrihydrite, synthetic goethite and synthetic 2L and 6L ferrihydrite. Experiences of Zn co-

193   precipitation and sorption onto ferrihydrite and goethite were also carried out. All ferrihydrite

194   and goethite syntheses were performed using previously developed protocols (Schulze, 1984;

195   Waychunas et al., 1993). X-ray absorption near-edge spectroscopy (XANES) spectra were

196   systematically recorded. In addition, if the concentration of the element targeted (Fe or Zn) in

197   the sample was sufficient, X-ray absorption fine structure spectroscopy (EXAFS) spectra

198   were also collected. Fe XANES and EXAFS spectra were recorded in the range 6962-7912

199   ev, in transmission mode. The monochromator used was a double Si(111)–Si(220) crystal. A

200   Fe foil was placed between the second and third ionization chamber for energy calibration.

201   Each sample was scanned between 6 and 10 times, to increase the signal-to-noise ratio in the

202   EXAFS region. All absorption spectra were calibrated according to the Fe K-edge position at

203   7128 eV corresponding to the maximum of the first derivative. EXAFS spectra were extracted

204   using a spline function adjusted by minimizing the Fourier transform magnitude at radial

205   distances <1 Å. EXAFS spectra were deglitched if necessary. Radial structure functions were

206   obtained by Fourier transform of the EXAFS spectra, using a Kaiser-Bessel apodization

207   function with a smoothing parameter of 3.0. Data reduction was done using the Iffefit

208   software package (Ravel and Newville, 2005).

209   The Fe-bearing minerals building up the composite samples were determined by linear

210   combination fit of the EXAFS spectra. The minimum number of components needed to

211   reproduce the EXAFS spectra was determined by principal components analysis (Manceau et

212   al., 2002) using the entire set of composite samples spectra. The minimum of the indicator

213   function (0.017) shows that two components are needed to reproduce the whole set of spectra

214   (Table 2).

215   Linear combinations were done between 3 and 11 Å^{-1} in the EXAFS region. During the

216   simulation, the following commonly used parameter was minimized:

$$R = \frac{\sum_{i=0}^{n}(data_i - fit_i)^2}{data^2} \times 100$$

217   Where n is the number of data point, $data_i$ is the data point number i, and fit_i is the fit value at

218   point i.

219   The sum of the wt.% of each compound obtained after least square fitting calculations was

220   also used as a goodness-of-fit parameter, since it should reach values close to 100 wt.% in a

221   reliable reconstitution.

222   For Zn, XANES spectra were recorded in fluorescence mode (multi-element Canberra Ge

223   detector), in the range 9511-10361 eV. Each sample was scanned 12 times and resulting

224   spectra were averaged.

225

226   2.3.6 Nuclear microprobe investigations

227   Textural information was provided by nuclear microprobe analyses on thin sections made

228   from samples collected at a precise depth. These experiments were performed using the

229   Laboratoire d'Etude des Eléments Légers nuclear microprobe in Saclay, France (Khodja et al.,

230   2001). µ-PIXE and µ-RBS analyses were carried out on Fe-bearing phases pre-selected by

231   SEM-EDS mapping. PIXE and RBS were used simultaneously to check the consistency of the

232   results. Analyses were performed with 3.07 MeV 4He+ (Isaure et al., 2001) and oxygen

233   quantified through resonant scattering. The size of the incident $^4He^+$ beam was approximately

234   4 x 4 μm^2. Prior analyses, both PIXE and RBS detection setups were calibrated with suitable

235   standards.

236   All measurements were performed by electrostatically scanning the beam on pre-selected

237   areas, and elemental contents from regions of interest were obtained by combining SIMNRA

238   software (Mayer, 1997) for RBS and GUPIXWIN software (Campbell et al., 2010) for PIXE.

239   Major and trace elements were quantified by µ-PIXE and oxygen by µ-RBS. H and C cannot

240   be quantified (only semi-quantification).

241

242   3. Results

243   3.1 Soil characteristics

244   The Technosol profile is made of several horizons of anthropogenic backfills from the surface

245   to ~190 cm (Figure 2). These backfills consist in successions of homogeneous yellow-white

246   pebbles horizons with heterogeneous backfills composed of a sandy brownish/darkish

247   material mixed with bricks and concrete fragments. Coal and slag fragments are also found in

248   these materials. Roots are present from the surface to ~170 cm depth. Below the backfill

249   materials, quaternary yellow silts are observed. Brick fragments were found at the transition

250   of the backfills and the quaternary silts (~200 cm). Below, the silts seem un-impacted by

251   human activities.

252 The Technosol investigated here belongs either to the sandy loam class or to the silt loam

253 class according to the FAO guideline for soil description (2006) because it contains 41-61%

254 sand, 30-50% silt and only 8% clay at maximum (Table 3). Total organic carbon is abundant

255 (> 20 g 100g^{-1}) over the whole profile, probably due to the coal fragments found in the

256 backfills. No particular biological investigation was performed, but it is noteworthy that no

257 earthworm activity was observed in the profile.

258 pH and CEC are similar for the three replicate samples located on a same horizon, indicating

259 that soil properties are homogeneous for a given depth. pH steadily increases with depth from

260 7.5 in surface sample to 8.5 in the deepest horizon. Oppositely, CEC decreases from ~23 meq

261 100 g^{-1} to 8-9 meq 100 g^{-1}. Fe concentrations vary from 6 to 2 wt. % in the profile, with no

262 specific trend with depth. Such generally high Fe concentration cannot be quantitatively

263 accounted for by the presence of crystalline Fe phases because hematite, the main Fe-bearing

264 mineral detected by XRD, accounts for 0-3 wt. % of the mineral assemblage (Table 4). Thus,

265 amorphous phases certainly contain Fe. Indeed, the mineralogical assemblage (Table 4) of the

266 Technosol is mainly composed of an amorphous phase which can be formed by organic

267 matter (Table 3) and contributes to 45-68 wt.% of the sample. Major minerals such as quartz

268 and calcite are also present. In addition to hematite, accessory phases are constituted of

269 phyllosilicates (illite, kaolinite) and sulphates (natrojarosite, syngenite). Such assemblage is

270 typical of oxidized slags (Navarro and Martínez, 2010). Note that this Technosol contains

271 significant amounts of trace metals such as Zn (Table 3), but also As and Pb (see total

272 concentrations in supplementary material).

273

274

275

276   3.2 Evolution of the Fe status along the profile

277   Fe status was first assessed by selective dissolution, using DCB and pyrophosphate methods

278   (Figure 3). The fraction of total Fe complexed to surfaces (including organic matter) is

279   negligible, as only 0.5-2 % of total Fe content is extracted by pyrophosphate, with no

280   dependence on depth in the profile. Contrastingly, 30-60 wt % of total Fe content is extracted

281   by DCB, indicating the presence of "free" Fe ("free" Fe covers different status: Fe oxides and

282   hydroxides as well as exchangeable Fe).

283   DCB results show that 20-30 % more of the total Fe is present as "free" Fe at the surface as

284   compared to the bottom of the profile. Such higher Fe extraction near surface could be due to

285   a depth-dependent mechanism of oxidation of primary Fe-bearing species. However, the

286   studied materials already contain oxides inherited from the past industrial activities, either

287   under crystallized (hematite) or glassy (amorphous phase) states, the latter having a typical

288   structure of melting-quenching, coming from slags (Figure 4). To distinguish between Fe

289   (hydr)oxides inherited from the past and (hydr)oxides newly precipitated since the deposit of

290   the backfills, XAS was employed.

291   A first analysis of all XANES spectra, collected on samples originating from various depths,

292   shows a high degree of similarity between them, witnessing generally similar Fe-bearing

293   phases and Fe oxidation state over the whole profile (Figure 5a). In particular, the pre-edge

294   features located at ∼10–20 eV before the edge jump and which are particularly sensitive to

295   the Fe oxidation state are similar for all samples, with a maximum located at ~7114.3 eV,

296   indicative of the predominance of Fe(III) species throughout the profile (Sundman et al.,

297   2014). Upon closer examination, however, the first derivatives shows a change with depth in

298   the respective contributions of two inflexion points at 7124 eV and 7128 eV. As the 7124 eV

299   and 7128 eV contributions are respectively attributable to Fe(II) and Fe(III) (Sundman et al.,

300 2014), such variations are attributed to a slightly higher contribution of Fe(II) in the lower

301 part of the profile and not to statistical fluctuations because the first derivative of XANES

302 spectra of two samples from a same horizon showed similar contributions of each inflexion

303 point (Figure 5b and c). SEM-EDS observation of a sample taken at 175-185 cm depth

304 (sample F1) evidenced the regular presence of particles of ~10 μm in width and containing

305 solely Fe and S (Figure 6). These Fe sulphides could be at the origin of the slightly higher

306 Fe(II) signal observed in depth by XANES. They were not detected by XAS and XRD (see

307 Table 4, Figure 5 and Figure 7) because of their minor abundance as compared to the other

308 Fe-bearing phases.

309 The mineralogy of the Fe-bearing phases was further assessed by least-square fitting of

310 EXAFS spectra. Assuming that the evolution as a function of depth is due to weathering, and

311 assuming that the sample collected in the bottom is representative of the lowest degree of

312 weathering, samples from the bottom to the top can be described as a mixture of the sample

313 from the bottom, plus additional component(s) that were formed during weathering. From

314 PCA analysis (see above), only two components are required to describe the whole system.

315 Following this approach, simulation of the spectra from samples collected in the surface

316 horizon (A1) and at intermediate depth (E1) was performed, assuming that they could be

317 described as a weighted sum of sample from the bottom (F1), plus an additional mineral that

318 results from weathering. For the surface sample, the best fit (Figure 7) was obtained with 77%

319 of sample from the bottom plus 25% of ferrihydrite. This is consistent with the DCB

320 extraction results, as the increase in the DCB-extractable fraction between depth (sample F)

321 and surface (sample A) was equal to 20-30%. Note that the sum of the weighted fraction of

322 the two components is close to 1, thus reinforcing the confidence in simulation results. For the

323 intermediate sample, the best fit (Figure 7) was obtained with 85% of sample from the bottom

324 plus 15% of ferrihydrite, confirming that ferrihydrite proportion decreases with depth.

325   These results indicate a change in the status of Fe along depth. An assumption is that this

326   change could influence the speciation of trace elements. The specific case of Zn is addressed

327   in this paper since it is present in significant concentrations (up to 4,000 µg g^{-1}) in the profile.

328   The status of Zn was investigated in relation with Fe but also with Mn status since Mn-

329   bearing phases can also be major scavengers of trace metals (Grangeon et al., 2012;

330   Koschinsky and Hein, 2003; Manceau et al., 2000; Peacock and Sherman, 2007).

331

332   3.3 Evolution of the Zn status along the Technosol profile and assessment of Zn mobility

333   The evolution of Zn speciation was first assessed using Zn-K edge XANES analysis of

334   composite samples, as it provides an integrating view. Data are presented as a function of

335   depth for two sets of replicate samples (Figure 8).

336   The XANES spectra are similar for each replicate samples, indicating that Zn speciation is

337   similar at any location at the same depth. Contrastingly, changes with depth are observed. The

338   contribution at 9668.5 eV is higher in the deepest samples (F1 and F3) whereas the peak at

339   9665.5 eV is more pronounced in the surface samples (A, C and E). In Zn-ferrihydrite

340   reference sample, the main contribution is located at 9665.5 eV. According to Cismasu et al.

341   (2013) and Waychunas et al. (2003), the position of the edge is indicative of Zn coordination.

342   When coordination is octahedral, the XANES spectrum only has one well defined edge,

343   whereas when coordination is tetrahedral, the XANES presents several maxima, as it is the

344   case here. Indeed, all XANES spectra have two maxima at ~9665.5 eV and ~9668.5 eV. Thus,

345   in presently studied samples, Zn coordination is tetrahedral. With increasing depth, the

346   intensity of the maximum at ~9665.5 eV relative to that at ~9668.5 eV evolves, and is lowest

347   at the maximum depth. As discussed by Waychunas et al., 2003, this is indicative of an

348   increasing number of heavy (*e.g.* Fe) scattering atoms around Zn, and thus of sorption to

349 better-crystallized phases. Consequently, in the deeper horizons, Zn is associated to phases

350 having a higher degree of crystallinity than in the surface horizons. This demonstrates that the

351 weathering processes during soil evolution influence Zn speciation, but do not necessarily

352 relate to Zn mobility as, for example, it gives no information on the solubility of the sorbing

353 phases. To study Zn mobility, and to compare this element to other major elements, leaching

354 of the composite samples was performed. The results indicate that Fe, Mn and Zn are all very

355 little labile throughout the whole profile (Figure 9). Thus, all these elements probably are

356 under the form of mineral phases (Fe, Mn) or strongly bound to mineral phases (Zn), which

357 are determined in the following.

358 Zn content was investigated first using pyrophosphate extraction, which showed that the

359 fraction of total complexed Zn, partly borne by organic matter is, within uncertainties,

360 constant and equal on average to 18% (Figure 10a). Thus, although organic matter is a

361 significant Zn reservoir, it does not represent the only Zn bearing-phase. The Zn content of

362 the DCB-soluble fraction was investigated next. Fe extraction yields are presented here above

363 (Figure 4b), and those from Mn and Zn are shown in Figure 10b. Both Zn and Mn are

364 significantly affected by DCB extraction. Zn extraction yield (35% on average) is, within

365 uncertainties, constant over the whole profile, while Mn has a slightly different behavior, $69 \pm$

366 4% being extracted in the first 40 cm depth, $51 \pm 6 \%$ at 120 cm depth and $62 \pm 4 \%$ at 180

367 cm depth (Figure 10b). As DCB solubilizes Mn (hydr)oxides (Mehra and Jackson, 1960), it

368 can be concluded that Mn is mainly present in the profile as discrete Mn (hydr)oxide(s). Here

369 above, it was shown that Fe is also mainly present as (hydr)oxides. These two (hydr)oxides

370 can potentially bear Zn, which is confirmed by the tetrahedral coordination of Zn assessed by

371 EXAFS. Note that, although within uncertainties, the fraction of Zn extracted by DCB might

372 increase with depth. However, as Zn concentration in the deepest sampling point (175-185 cm

373 depth) is 10 times lower that in the surface horizon (0-10 cm depth), and even 26 times lower

than in the sampling point just above (110-130 cm depth), a small quantity of Fe and Mn

(hydr)oxides that would have migrated from the upper horizons (or a limited contamination,

for example during sampling) may have led to such apparent slight change extraction yield.

According to this assumption, Zn is probably associated in depth with the Fe (hydr)oxides

originally present in the backfills, but also with the newly formed Fe (hydr)oxides at the

surface of the profile that would have migrated.

To summarize, in this profile and on average, less than 0.1 % of total Zn is H_2O-extractable,

up to 18 % of total Zn would be bound to organic matter, 35 % of total Zn would be adsorbed

onto Fe/Mn (hydr)oxides, and about 47 % of total Zn is present under a residual form (that

cannot be accessed with any of the extractant used here). To better constrain this distribution,

μ-PIXE and μ-RBS are now used with a twofold aim: first, cross-check results from chemical

extraction and in particular the association between Zn and Fe/Mn pedogenic (hydr)oxides,

second, determine the nature of the residual form. These analyses were performed on sample

LM2 sample (90 cm depth).

The association between Zn and Fe (hydr)oxides could be straightforwardly and regularly

observed, as exemplified in Figure 11. The grain showed in this image is made of coal, with a

Fe coating having a size of about 50 μm on the edge. The morphology suggests that the Fe

(hydr)oxide is a secondary phase and was formed during soil evolution. Using quantitative

analyses performed two regions of interest (ROI – Table 5), this Fe (hydr)oxide is probably

the ferrihydrite identified using EXAFS spectroscopy, since Fe/O atomic ratios in the two

ROIs (respectively 0.42 and 0.51) are lower than the theoretical Fe/O ratio of hematite (0.66),

but are consistent with Fe/O ratio of ferrihydrite (theoretical value from 0.42 to 0.57

depending on the hydration state). Table 5 indicates also that Zn/Fe atomic ratio could reach

up to 17%, which further confirms that ferryhydrite is a very efficient sink for metallic trace

elements.

399   The nature of the Zn-bearing phase forming the residual phase was found to be complex, as

400   demonstrated in Figure 12 and Table 6, where complex associations between Zn, Mn, Fe, S

401   and O could be quantified. The quantitative analysis carried out in some regions of interest

402   (ROI) show various elemental proportions (Table 6). The grain is composed of different Fe-

403   compounds: Fe (hydr)oxides (ROI 3,4,6) and Mn, Zn, Fe-bearing sulphates (ROI 1 and 5).

404   Interestingly, these latter are likely a mix of sulphides undergoing oxidation and forming

405   sulphates (see the white arrow in Figure 12 b and c), since the S/O ratio of 0.42 (ROI 1 and 5),

406   are higher than the expected ratio in a sulphate (0.25). It is interesting to note that the external

407   part of the grain (ROI 3 and 4) do not contain sulphur. It is only composed of Fe (hydr)oxides,

408   and contain less than 0.2 atomic percent of Zn. Fe/O atomic ratio calculated for all the Fe

409   (hydr)oxides (see Table 6) range from 0.45 to 0.48. These values are lower than Fe/O ratio of

410   hematite (0.66) and goethite (0.5), but are consistent with Fe/O ratio of ferrihydrite (0.42-0.57

411   depending on the hydration state).

412

413   4. Discussion

414   The study of the Fe status by several methods of investigation throughout the Technosol

415   profile indicates that (i) Fe is mainly under Fe(III) form, with a contribution of Fe(II) in the

416   deeper samples, (ii) some Fe species inherited from the past have been oxidized and

417   secondary minerals are constituted of Fe-bearing sulphates (jarosite) and Fe (hydr)oxides, (iii)

418   Fe(III) is mainly under the form of ferrihydrite, as evidenced by XAS, μ-PIXE and μ-RBS

419   (iv) 20 to 30% more Fe (hydr)oxides are present in the surface than in depth. Ferrihydrite

420   forms coatings surrounding different grains of the Technosol, in consistence with a

421   neoformation induced by weathering processes. Previous studies have shown that in slags,

422   secondary minerals formed by oxidation can be present as coatings on surfaces and as

423   precipitates of various phases such as amorphous Fe, Al (hydr)oxides, chalcanthite, siderotil,

424   jarosite, brochantite or gypsum (Navarro and Martínez, 2010; Piatak et al., 2004). Fe sulphate

425   and Fe (hydr)oxides are both secondary minerals formed by oxidation of Fe-bearing sulphides

426   (Blowes et al., 2005). Such reaction typical of acid mine drainage can be encountered in all

427   kind of wastes containing sulphides. In the present study, this assumption is consistent with

428   the sulphates found by XRD and μ-PIXE, as well as the Fe sulphides encountered in depth

429   (see Figure 6 above). However, the pH remains near-neutral to slightly basic since the net-

430   acid-generating potential was probably exceeded by the net-neutralizing potential due to a low

431   sulphide/neutralizing minerals ratio (e.g. Plante et al., 2011). Thus, the main evolution driver

432   of this 100 years-old Technosol is oxidation, which affects the Fe status, the CEC and the

433   related trace elements mobility. The presence of free Fe at the surface of this Technosol is of

434   interest since it provides the soil with an efficient trace metals sink and since such Fe is easily

435   accessible to plants (Pansu and Gautheyrou, 2006). According to Navarro and Martínez

436   (2010), the formation of secondary phases (*e.g.* jarosite, gypsum, goethite, ferrihydrite) may

437   control the distribution of trace elements in the pore water and the degree to which they are

438   mobilized into the environment. Dissolution of primary minerals leads to trace elements

439   release in pore water solution. These trace elements can precipitate to form secondary

440   minerals, or can be sorbed onto these secondary minerals.

441   In the studied Technosol, XANES revealed that Zn has tetrahedral coordination and is sorbed

442   to phases of increasing crystallinity when depth increases. This could indicate that the

443   amorphous Fe (hydr)oxides inherited from the past are slightly more crystalline than the

444   newly formed Fe (hydr)oxides at the surface. Soil formation on such material does not induce

445   a dramatic increase of Zn solubility since efficient scavengers are concomitantly formed in the

446   system. Zn-bearing phases identified in the present study are: complex Fe, Mn, Zn sulphides,

447   which may be the primary Zn-bearing phase, sulphates which may be the oxidation product of

448   the sulphides, organic matter, and ferrihydrite. On the contrary, no Zn-bearing Mn

449   (hydr)oxides were found, even if there are known to be important sinks of trace elements such

450   as Zn.

451   The assumption that the deeper horizons are the parent material in this Technosol profile is

452   difficult to prove since the characteristics of the original material at the time of backfill

453   deposit are unknown. However, the observed evolution of Fe mineralogy with depth, as well

454   as Zn speciation change and CEC decrease with depth, is a clue for the validity of this

455   assumption.

456   This study also highlights that DCB selective extraction method is relevant to investigate Fe

457   status in a Technosol, since the relative proportion of "free" Fe - mainly Fe (hydr)oxides -

458   quantified by DCB (20-30% in surface) is similar to the ones estimated by EXAFS linear

459   combination fitting (25% in surface). DCB is also interesting to assess the relations between

460   all the "free" Fe species and trace elements such as Zn, even if the concentrations of Zn bound

461   to Fe (hydr)oxides are probably underestimated by this extraction. Indeed, dithionites are

462   labile compounds which undergo rapid disproportionation in aqueous solution due to their

463   sensitivity to oxygen. This decomposition is rapid at pH < 5.5 but also occur at neutral and

464   basic pH (de Carvalho and Schwedt, 2001). It produces mainly thiosulphate and bisulphite

465   which will be the final product of the disproportionation. But intermediate sulphide and

466   elemental sulfur, playing a catalytic role, are also encountered in solution as minor

467   decomposition products (de Carvalho and Schwedt, 2001; Wayman and Lem, 1970).

468   Dissolved sulphide can react with Zn to precipitate ZnS during DCB extraction (Rao et al.,

469   2008). This would explain the gap between DCB results which show that only 35% of total

470   Zn is dissolved whereas XANES and nuclear microprobe indicate a major contribution of Zn

471   associated with ferrihydrite.

472   In the future, this Technosol will potentially evolve again because some phases are not

473   thermodynamically stable in conditions of pH observed here. For instance, jarosite is known

474   to be stable at pH<3 (Blowes et al., 2005), whereas the pH in the Technosol is near-neutral to

475   slightly basic. Moreover, the input of organic matter at the surface based on organic C

476   determination, is slightly visible after 100 years of evolution. Pyrophosphate extractions have

477   shown that Fe and Zn are variably complexed to surfaces (including organic matter).

478   However, the pyrophosphate extract does not only determine organic forms but also dissolves

479   poorly crystalline mineral phases (e.g. Kaiser and Zech, 1996). Mineralogical investigations

480   confirmed that Fe and Zn are not complexed on coal which is the most abundant carbon phase

481   of the Technosol. Indeed, Fe and Zn were not observed at the surface of the coal grains (see

482   Figure 11). Though, other clues of evolution are visible in the studied Technosol. CEC is

483   higher near surface and could indicate that the soil surface reached a higher evolution stage

484   than the deeper horizons, either due to weathering or to bioturbation. Organic matter will

485   probably play an important role in the future on major and trace element speciation.

486

487   5. Conclusions and environmental implications

488   Technosols are highly heterogenous and widely differ from one place to another because of

489   the variety of their constitutive man-made materials. In this study, a Technosol made of

490   smelter slags, i.e. containing high amounts of coal and Fe (hydr)oxides was characterized. The

491   results indicate that 100 years of soil evolution has led to the precipitation of secondary

492   minerals (including Fe (hyrdr)oxides and Fe sulphates) at the surface of the profile. This

493   behavior is similar to pedogenic processes occurring in natural soils, but other specific

494   evolutions due to large thermodynamic disequilibrium can be highlighted, in particular

495   sulphide oxidation and sulphate precipitation. This specific behavior of Technosols over time

496   can be generalized to all kinds of Technosols, even if the final reaction products are not

497   similar. Such evolution influences pollutants mobility including trace elements release. In this

498   specific study, Technosol evolution does not induce a dramatic increase of Zn solubility since

499   efficient scavengers are concomitantly formed in the system. However, this behavior is not

500   generic and will depend on the type of Technosol and on the secondary minerals formed as

501   well as on the nature and amount of organic matter. If the trace metals sinks are not abundant

502   and/or efficient, this could potentially represent a risk of mobilization of trace metals. This

503   must be carefully examined through case studies.

Table 1 Summary of selective dissolution procedures (from Bataillard et al., 2014)

Fraction	Reagent	Shaking time and temperature
Citrate-bicarbonate-dithionite (CBD)	0.3 M Na Citrate pH 7.3+$Na_2S_2O_4$+NaCl saturated solution	1 g DM moist sediment/10 ml 0.3 M NaCitrate pH 7.3+0.4 g $Na_2S_2O_4$+2 mL NaCl saturated solution Heat 15 min 80 °C Centrifugation 5 min at about 3,000 g Repeated twice
Sodium pyrophosphate	0.05 M $Na_4O_7P_2$	2 g DM moist sediment/200 ml $Na_4O_7P_2$ Agitation 16 H, 20 °C±5 °C. Centrifugation 20 min 18,000 rpm

Table 2: Results of the principal component analysis on the 8 composite sample spectra. The minimum of the indicator (IND) function shows that two components are needed to reproduce the whole set of spectra.

Component	Eigenvalue	IND[a]
1	13.7	0.018
2	1.7	0.017
3	0.9	0.022
4	0.8	0.028
5	0.6	0.040
6	0.4	0.085
7	0.4	0.32

Table 4. Relative proportion of crystalline minerals in the bulk composite samples of the Technosol profil estimated by Rietveld analysis (ND: not detected)

Mineral proportion (wt.%)[a]	A1	C1	E1	F1
Quartz	31	14	15	23
Calcite	4	2	1	5
Albite	2	1	<1	1
Microcline	1	<1	<1	1
Dolomite	4	1	1	ND
Natrojarosite	<1	<1	ND	1
Hematite	2	3	<1	1
Mullite	3	3	2	1
Syngenite	1	<1	<1	<1
Illite/mica	4	4	10	6
Kaolinite	3	4	4	1
Amorphous phase	45	68	67	60

[a]Error on these results: +/- 5 wt%

Table 5. Quantitative elementary results obtained by µ-PIXE and µ-RBS on two regions of interests (ROI) of the grain in the isolated sample LM2 as shown in Figure 11.

Atomic fraction (%)	ROI 1	ROI 2
O[a]	36.6	30.4
Si[b]	2.4	6.3
P[b]	0.3	0.7
S[b]	0.8	0.9
Cl[b]	0	0
K[b]	0	0.1
Ca[b]	0.1	0.6
Ti[b]	0	0
Mn[b]	0	0
Fe[b]	18.8	12.6
Zn[b]	0.7	2.1
As[b]	0	0
Pb[b]	0.2	0.2
Fe/O atomic ratio	0.51	0.42

[a] Error on O is ± 5%

[b]Error on these elements is comprised between 1 and 5% when the atomic fraction is lower than 1%, elsewhere the error is lower than 1%.

Table 6. Quantitative elementary results obtained by μ-PIXE and μ-RBS on five regions of interests (ROI) of the grain in the isolated sample LM2 as shown in Figure 12.

Atomic fraction (%)	ROI 1	ROI 2	ROI 3	ROI 4	ROI 5
O[a]	36.2	40.2	40	34.2	37.8
Si[b]	13.8	0.5	0.2	13.4	0.6
P[b]	0	0.5	0.1	0.2	0.1
S[b]	15.3	0.2	0.1	14.0	0.9
Cl[b]	0.2	0	0	0	0.1
K[b]	0.3	0	0	0.2	0
Ca[b]	2.2	0.3	0.2	1.7	0.1
Ti[b]	0.2	0	0	0.1	0
Mn[b]	3.0	0	0	2.0	0
Fe[b]	3.8	18.1	19.0	4.6	17.2
Zn[b]	7.5	0.2	0.1	6.5	0.1
As[b]	0	0.1	0	0	0
Pb[b]	0.8	0	0	0	0
Fe/O atomic ratio	-	0.45	0.48	-	0.46

[a] Error on O is ± 5%

[b] Error on these elements is comprised between 1 and 13% when the atomic fraction is lower than 1%, elsewhere the error is lower than 1%.
