On the Impact of Beamforming Strategy on mm-Wave Localization Performance Limits

Anna Guerra, Member, IEEE, Francesco Guidi, Member, IEEE, Davide Dardari Senior Member, IEEE

Abstract—In this paper we investigate the localization performance limits of massive arrays working at millimeter-wave (mm-wave) frequencies and adopting two different beamforming strategies. In the first one, array weights are set in order to point towards a precise direction (classic beamforming), whereas in the second one, such weights are randomly chosen (random beamforming). Thanks to the large set of measurements as well as the high angular resolution provided by massive arrays, only one single anchor node can be used for localization estimation, thus avoiding over-sized infrastructures dedicated to positioning. Accounting for such beamforming strategies, performance is evaluated by taking into account the effects of arrays orientation and beamforming weights non-idealities arising when the number of antennas is high and low-complex components are adopted. Results reveal that classical beamforming outperforms the random one which still remains a feasible solution when the system complexity has to be kept affordable.

Index Terms—Position Error Bound, Millimeter-wave, Massive array, 3D localization.

I. INTRODUCTION

Fifth generation personal devices will be required to perform self-localization in indoor environments as well as to share a huge amount of data at extremely high rates [1]. To face these challenges, massive arrays and mm-wave frequencies emerge like potential candidates for including a large number of antennas in a small size with the possibility to focus the array beam in a precise direction in space [2]–[4]. In this context, an access point (AP) equipped with a massive array could be in principle used as a single-anchor node, i.e., a node whose position is a-priori known, permitting the mobile users to be aware of their positions, and, thus, enabling new applications such as those related to augmented reality and cyber-physical systems, as depicted in Fig. 1. Moreover, when operating at such high frequencies, the portable devices can also adopt massive arrays as the reduced wavelength permits to pack a large number of antennas in small spaces, as for example smartphones or tablets [5]–[7].

Different works deal with the derivation of the Cramer-Rao Lower Bound (CRLB) as a tool to investigate the ultimate performance of a localization system [8]–[14]. Notably, the CRLB can be considered as an asymptotic lower bound for all estimators and it can be asymptotically achieved, for example, by the maximum likelihood estimator (MLE) operating in high signal-to-noise ratio (SNR) regime. Therefore, here we aim at presenting the localization performance as a benchmark for real estimators without providing new localization techniques as done, for example, in some or our previous works [15]. In [8], [9], the Position Error Bound (PEB) is derived for a wideband sensors network composed of several anchors and multipath effects are taken into account in the analysis. Nevertheless, in these works, beamforming strategies are completely neglected as anchors were considered equipped with a single antenna unable to perform beamsteering operations. Moreover, even if considered as a virtual array, anchors operate independently to each other as in multiple-input multiple-output (MIMO) systems. In our previous work [14], some preliminary results on positioning accuracy have been presented for different fractional bandwidth and spherical arrays.

Stimulated by this framework, in this paper we propose a PEB study to compare the localization capabilities of mm-wave massive arrays operating different beamforming strategies. More specifically, classical and random beamforming will be compared in terms of positioning performance. In both cases, a phased array composed of phase shifters (PSs) is considered, as reported in Fig. 2. In the first strategy, all the beamforming weights are set in order to point towards a precise direction, e.g., the AP, while in the second one, the weights are randomly chosen. From a radiation pattern point-of-view, classical beamforming permits to accurately shape the radiation pattern radiation pattern with a main narrow beam in the intended direction. Differently, random beamforming results in a non-defined pattern shape but, at the same time, it permits to maintain a certain level of diversity gain while...
keeping the architecture complexity lower. In fact, as shown in [16]–[18], where transmitarrays (i.e., a particular type of phased arrays consisting of a focal source illuminating a planar array) have been proposed, PSs are usually realized using switches. Therefore, as it is often undesirable to obtain a continuous phase value ranging from 0° to 360° with real antennas, the resulting quantization errors should be taken into account in the analysis. Thus, this paper proposes a CRLB-based investigation on how a proper choice of the beamforming strategy can lead to different levels of localization accuracy and of array complexity.

The rest of the paper is organized as follows. In Sec. II we describe the considered array configurations, whereas in Sec. III we discussed an ad-hoc signal model for the analyzed multi-antennas schemes. Sec. IV shows the PEB derivation, and of array complexity.

II. ANTENNA ARRAY GEOMETRIC CONFIGURATION

We consider a 3D localization scenario consisting of a $N_{rx}$-sized receiving array located in known position (i.e., $p_t^i = [x_0^i, y_0^i, z_0^i]^T = [0, 0, 0]^T$) and a transmitting array with $N_{tx}$ antennas whose position, $p_i = [x_i^t, y_i^t, z_i^t]^T = [x, y, z]^T$, is to be inferred by the estimation process. We indicate with $\theta = [\theta, \phi]^T$ the direction-of-arrival (DOA), i.e., the angle formed between the two arrays geometric centers. Moreover, if classical beamforming is considered, the steering angles will be indicated with $\theta_0 = [\theta_0, \phi_0]^T$.

In both arrays, the antennas coordinates with respect to the array centroid can be expressed as

$$p_{i/m}^t(\theta^t) = \begin{bmatrix} x_{i/m}^t, y_{i/m}^t, z_{i/m}^t \end{bmatrix}^T = \rho^t_{i/m} R(\theta^t) d^t(\rho^t_{i/m})$$

with $i = 1, 2, \ldots, N_{tx}$, $m = 1, 2, \ldots, N_{rx}$ being the 1D transmitter (TX)/receiver (RX) antenna index, $R(\theta^t)$ being the 3D rotational matrix with $\theta^t = [\theta_0^t, \phi_0^t]^T$ being the transmitting/receiving array orientation with respect to its geometric center. The direction cosine in (1) is given by

$$d(\theta) = [\sin(\theta) \cos(\phi), \sin(\theta) \sin(\phi), \cos(\theta)]^T.$$ (2)

Finally, $\rho_{i/m}^t = \|p_{i/m}^t(\theta^t) - p^i\|_2$ and $\theta_{i/m}^t = [\theta_{i/m}^t, \phi_{i/m}^t]^T$ represent the transmitting/receiving spherical coordinates.

Having indicated with $D$ the maximum diameter and with $d = \|p^i - p^j\|_2$ the distance between the two arrays, we suppose that they are sufficiently far from each other, i.e., $D \ll d$, in order to assume an identical angle of incidence at all the array antennas. Note that this hypothesis is especially verified at mm-wave where the array dimensions are very small thanks to the reduced wavelength. Given this assumption, it is possible to express the propagation delay and the amplitude between the $m$th receiving and the $i$th transmitting antenna, respectively, as

1) $\tau_{im} \approx \tau + \tau_{im}^t(\theta, \phi) - \tau_{im}^r(\theta, \phi)$
2) $a_{im} \approx a$

where $\tau_{im} \triangleq \|p_m^i - p_i^j\|_2/c$ is the time-of-arrival (TOA) between the $m$th receiving and the $i$th transmitting antenna,

$$\sqrt{c} \hat{D} f \triangleq \|p_i^j - p_i^j\|_2/c = d/c$$

is the TOA between the arrays centers and $\tau_{im}^t(\theta, \phi^i) = \tau_{im}^r(\theta, \phi^j)$ is the transmitting/receiving inter-antenna delay given by

$$\tau_{im}(\theta, \phi) = \frac{1}{c} d(\theta) \rho_{i/m}^t(\theta, \phi^i)$$ (4)

with $c$ being the speed of light.

III. BEAMFORMING SCHEMES AND SIGNAL MODEL

In this section, the two array beamforming strategies present in Fig. 2 will be analysed from a signal processing point-of-view and by focusing on how the different signaling phasing schemes translate in different localization capabilities.

A. Transmitted Signal Model and Beamforming

The transmitted signal at the $i$th transmitting antenna is denoted with $g(t) = \sqrt{E} \Re \{p(t) e^{j2\pi f_{c} t}\}$ with $p(t)$ being the unitary energy equivalent low-pass signal, and $f_{c}$ the carrier frequency. We consider a constraint on the total transmitted energy $E_{tot}$ which is uniformly allocated among antennas, thus $E = E_{tot}/N_{tx}$ represents the normalized energy at each antenna element. We introduce the Fourier transform of $p(t)$ as $P(f) = \mathcal{F}\{p(t)\}$, with $\mathcal{F}\{\cdot\}$ denoting the Fourier transform operation in a suitable observation interval $T_{obs}$. For further convenience, the vector $p(f) = P(f) 1_{N_{tx}\times1}$ contains all the baseband transmitted signals with $1_{N_{tx}\times1}$ being a $N_{tx}$-sized vector of all ones.

In multi-antenna systems, beamforming is obtained by applying different weights at each array element. In classical beamforming, the objective of this operation is to coherently sum up signals towards the intended steering direction, i.e. $\theta_0$. Considering the signal bandwidth $W$, when $W \ll f_{c}$ holds, this process can be realized using only PSs. The corresponding array structure is referred as phased array. Contrarily, in random beamforming, weights are randomly generated resulting in a non-directive radiation pattern but in an extremely low-complexity array design. In both cases, the beamforming weights are collected in a matrix that can be defined as

$$B = \text{diag}(\omega_1, \omega_2, \ldots, \omega_1, \ldots, \omega_{N_{tx}})$$

where the $i$th PS generic element can be written as

$$\omega_i = \begin{cases} e^{j2\pi f_{c} \tau_{im}(\theta_0)} & \text{Classical Beam} \\ e^{j \nu_i} & \text{Random Beam} \end{cases}$$ (6)

Fig. 2. Classical and random beamforming schemes.

$\tau \triangleq \|p_i^j - p_i^j\|_2/c = d/c$ is the TOA between the arrays centers and $\tau_{im}(\theta, \phi^i) = \tau_{im}(\theta, \phi^j)$ is the transmitting/receiving inter-antenna delay given by

$$\tau_{im}(\theta, \phi^i) = \frac{1}{c} d(\theta) \rho_{i/m}^t(\theta, \phi^i)$$ (4)

with $c$ being the speed of light.
with \( v_i \) uniformly distributed between 0 and 2\( \pi \), i.e., \( v_i \sim U(0, 2\pi) \).

In addition, even when classical beamforming is adopted, some technological issues could induce errors in the beamforming vector resulting in an increased side-lobe level (SLL), decreased array maximum gain and angular resolution. In fact, in practical implementations, digitally controlled PSs are often adopted in place of their high-resolution analog counterparts inducing quantization errors, to be accounted for in the localization performance analysis [19].

In the presence of such non-perfect weights, a matrix accounting for non-idealities is introduced

\[
Q = \text{diag}(\varsigma_1, \varsigma_2, \ldots, \varsigma_i, \ldots, \varsigma_{N_a})
\]

where \( \varsigma_i \) takes into account the \( i \)th beamforming weight quantization error, i.e., \( \varsigma_i = \exp(j\delta_i^\psi) \) with \( \delta_i^\psi \) being the phase error. For further convenience, let indicate with \( \tilde{\omega}_i = \exp(j(\mu_i^r(\theta_0) + \delta_i^\psi)) \) the quantized weights in classical beamforming; whereas \( \omega_i \) in random beamforming.

### B. Received Signal Model

All the received signals are gathered in a vector \( r(f) = [R_1(f), \ldots, R_m(f), \ldots, R_{N_t}(f)]^\top \), where \( R_m(f) = \mathcal{F}\{t_m(t)\} \) is evaluated in \( T_{obb} \) and \( r_m(t) \) is the equivalent low-pass received signal at the \( m \)th receiving antenna. Specifically, the received signal vector can be written as

\[
r(f) = x(f) + n(f),
\]

where the set of useful received signals is

\[
x(f) = [X_1(f), \ldots, X_m(f), \ldots, X_{N_t}(f)]^\top
\]

\[
= \sqrt{E} \alpha(f, \theta, \vartheta^f) c(f, \tau) A^f(f, \theta, \vartheta^f) Q B p(f)
\]

and \( n(f) = [N_1(f), \ldots, N_m(f), \ldots, N_{N_t}(f)]^\top \) is the noise vector with \( N_m(f) = \mathcal{F}\{n_m(t)\} \), with \( n_m(t) \sim CN(0, \sigma_n^2) \) being a circularly symmetric, zero-mean, complex Gaussian noise. The receiving and transmitting direction matrices for the inter-antennas delays and TX orientation are

\[
a^f(f, \theta, \vartheta^f) = \begin{bmatrix} e^{j\gamma_1}, \ldots, e^{j\gamma_m}, \ldots, e^{j\gamma_{N_t}} \end{bmatrix}^\top
\]

\[
A^f(f, \theta, \vartheta^f) = \text{diag}\left( e^{-j\gamma_1}, \ldots, e^{-j\gamma_m}, \ldots, e^{-j\gamma_{N_t}} \right)
\]

with \( \gamma_{i/m} = 2\pi(f + f_k) \omega_{i/m}(\theta, \vartheta^\psi) \). The channel vector is indicated with \( c(f, \tau) = \alpha 1_{x \times N_t} \) being the \( 1 \times N_t \), whose generic element is \( \alpha = \alpha \exp(-j2\pi(f + f_k)\tau) \). For further convenience, define \( \nu_f = E_x/N_0 = \nu N_a \), with \( \nu = E/N_0 \). The SNR at each receiving antenna element is

\[
\text{SNR}_r = N_0\text{SNR}_\nu, \text{ where } \text{SNR}_\nu = a^2\nu \text{ represents the SNR component related to the direct path between a generic couple of TX-RX antenna elements.}
\]

### IV. Position Error Bound

In the following, we will derive the asymptotic limits of the TX position (i.e., \( p^i \)) estimation error starting from the set of received waveforms \( r(f) \). Thus, we define the unknown parameters vector as \( \varphi = [p^i]^\top, \theta]^\top \). We assume that an initial search between the TX and RX is conducted in order to coarsely infer the TX position and to allow the TX setting its own beamforming weights to point towards the RX in the case in which classical beamforming is operated.

The performance of any unbiased estimator \( \hat{\varphi} = \hat{\psi}(r(f)) \) can be bounded by the Cramer-Rao bound (CRB) defined as [20]

\[
\text{E}_{\varphi,\vartheta} \left\{ \left| \frac{\partial}{\partial \varphi} \ln f(r|\psi) \right| \right\} \geq J^{-1}_{\varphi} \text{CRB}(\varphi) \tag{11}
\]

where \( J_{\varphi} \) is the Fisher Information Matrix (FIM) given by

\[
J_{\varphi} = -\text{E}_{\varphi,\vartheta} \left\{ \nabla_\psi^2 \ln f(r|\psi) \right\} = \begin{bmatrix} J_{pp} & J_{pa} \\ J_{ap} & J_{aa} \end{bmatrix}
\]

with the symbol \( \nabla_\psi^2 \) indicating the second partial derivatives with respect to the elements in \( \psi \) and

\[
J_{pp} = \begin{bmatrix} J_{xx} & J_{xy} \\ J_{yx} & J_{yy} \end{bmatrix}, \ J_{pa} = \begin{bmatrix} J_{xa} \\ J_{ya} \end{bmatrix}, \ J_{aa} = \begin{bmatrix} J_{aa} \end{bmatrix}.
\]

Since the observations at each receiving antenna element are independent, the log-likelihood function \( \ln f(r|\psi) \) can be written as

\[
\ln f(r|\psi) \propto -\frac{1}{N_0} \sum_{m=1}^{N_t} \int_W |R_m(f) - X_m(f)|^2 df.
\]

According to (12)-(14), it is possible to compute the elements of the FIMs as

\[
J_{pp} = 8\pi^2 \nu a^2 \sum_{mij} \Re \{ \tilde{\omega}_{ij} \tilde{\chi}_i(2) \} \nabla_{\tau_{im}} \nabla_{\tau_{jm}} \tag{15}
\]

\[
J_{aa} = 4\pi \nu a \sum_{mij} \Im \{ \tilde{\omega}_{ij} \tilde{\chi}_i(1) \} \nabla_{\tau_{im}} \nabla_{\tau_{jm}}
\]

where \( \nu_{a/b} \) indicate two elements in the set \( \{ x, y, z \} \), \( \sum_{mij} = \sum_{m=1}^{N_t} \sum_{i=1}^{N_a} \sum_{j=1}^{N_a} \), \( \tilde{\omega}_{ij} = \omega_i \tilde{\omega}_j \), \( \tilde{\chi}_i = e^{-j2\pi f_{\Delta_{\tau i}}} \), \( \Delta_{\tau i} = \tau_{im} - \tau_{jm} \), and

\[
\chi_{i,j}(2) = \int_W (f + f_k) e^{-j2\pi f_{\Delta_{\tau i}}} |P(f)|^2 df
\]

\[
\chi_{i,j}(1) = \int_W (f + f_k) e^{-j2\pi f_{\Delta_{\tau i}}} |P(f)|^2 df
\]

\[
R_{ij}^{a}(\Delta_{\tau i}) = \int_W e^{-j2\pi f_{\Delta_{\tau i}}} |P(f)|^2 df
\]

The derivatives translating the TOA and DOA in position information can be expressed as

\[
\nabla_{\tau_{im}} = \frac{1}{e} \left\{ c \nabla_p(\tau) + \nabla_p(\phi) \begin{bmatrix} p_i^a(\theta)^\top - p_i^a(\theta^f) \end{bmatrix} \right\}
\]

with

\[
\nabla_p(\phi) = \begin{bmatrix} \cos(\phi) \\ \sin(\phi) \\ -\tan(\theta) \end{bmatrix}^\top
\]

\[
\nabla_p(\phi)^\top = \begin{bmatrix} -\sin(\phi) \\ \cos(\phi) \\ 0 \end{bmatrix}^\top.
\]
Moreover, by further analyzing (15), one can notice the dependence of the FIM from the beamforming weights given by the coefficients \( \hat{\omega}_{ij} \).

Finally, by using the Schur complement, the PEB expression can be easily derived as

\[
\text{PEB} = \sqrt{\text{tr} \left( \text{CRB} (p') \right)} = \sqrt{\text{tr} \left( (J_{pp} - J_{pa} J_{au}^{-1} J_{pu}^{-1} J_{po}^{-1})^{-1} \right)}
\]

(20)

where \( \text{tr} (\cdot) \) is the trace operation.

Equation (20) is a general bound valid for any beamforming strategy and accounting for signal weights quantization effects. Specialized expressions can be derived from (20) for specific cases to get insights on the key parameters affecting the performance as it will be done in the following.

A. Absence of Quantized Weights in Classical Beamforming

Here we provide an example on how the general expression (20) can be simplified in absence of beamforming weights errors. Given the FIM in (15), it can be easily found that for classical beamforming it is

\[
\text{PEB} = \sqrt{\text{tr} \left( G^{-1} J_{pp}^{-1} \right)}
\]

(21)

where we have separated the effect of signal design \( J_{pp} \) (i.e., that related to (16)) from that of the geometry \( G \) (i.e., that related to (17)). Specifically for phased arrays, we have

\[
J_{pp} = 8\pi^2 \text{SNR}_1 (\beta^2 + f_c^2)
\]

(22)

\[
G = \sum_{mij} \nabla_{pp} (\tau_{im}, \tau_{jm})
\]

(23)

where \( \nabla_{pp} (\tau_{im}, \tau_{jm}) \) is a 3 \times 3 matrix and \( \beta^2 \) is the squared baseband effective bandwidth of \( p(t) \).

The matrix \( G \) provides, through derivatives, the relationship between the TOA-DOA at each TX-RX antenna element couple and the TX position. To improve the comprehension of (21), in the next paragraph the particular case of planar arrays will be discussed considering a fixed orientation \( \phi' = \phi = [0, 0, 0]^T \).

1) Special Case: Planar Array: For squared arrays with antennas spaced of \( d_{\text{ant}} \), we can compute a simplified version of (17). Specifically, it is possible to obtain:

\[
\nabla_p (\tau_{im}) = \frac{1}{c} \left[ (i_x - m_x) \nabla_p (\phi) + (m_z - i_z) \nabla_p (\theta) \right]
\]

(24)

with \( m_x = m_z = -\frac{N_x}{2}, \ldots, \frac{N_x}{2} \) and \( i_x = i_z = j_x = j_z = -\frac{N_x}{2}, \ldots, \frac{N_x}{2} \). From (24), it is straightforward to derive (19). Then, by considering the summations present in (22), it is possible to obtain the elements of the position CRB matrix as

\[
\text{CRB} (x) = \text{CRB} (z) = \text{CRB}_0 \frac{12}{S N_{\text{tx}} (N_{\text{rx}} - 1)}
\]

\[
\text{CRB} (y) = \frac{\text{CRB}_0}{N_{\text{tx}} N_{\text{rx}}}
\]

(25)

where \( \text{CRB}_0 \) represents the CRB of the ranging error one would obtain using single antenna which can be written as

\[
\text{CRB}_0 = \frac{c^2}{8\pi^2 \text{SNR}_1 (\beta^2 + f_c^2)}
\]

(26)

and \( S = A'/y^2 \) with \( A' = N_{\text{tx}} d_{\text{ant}} \).

From (25) it is possible to remark that the CRB of the estimation error in the \( y \)-coordinate is inversely proportional to \( N_{\text{tx}} \) and \( N_{\text{rx}} \); in fact, the \( N_{\text{rx}} \) term accounts for the SNR enhancement due to the beamforming process while the \( N_{\text{tx}} \) term accounts for the number of independent measurements available at the RX.

V. NUMERICAL RESULTS

In this section, numerical results are reported considering the two discussed beamforming schemes. For what the antennas spatial deployment is regarded, planar arrays are accounted for as they represent the most conventional structure to be integrated in small-sized devices. Differently from Sec. IV-A1, here we compare results with fixed and averaged RX orientations, thus giving the possibility to appreciate the impact of the array rotation on the localization performance.

We consider a scenario with a single RX with the centroid \( \phi' = [0, 0, 0]^T \), and a TX located in \( \phi' = [0, 5, 0]^T \) \( (d = 5 \text{m}) \). As previously assumed, the RX has a perfect knowledge of the TX steering direction.

Results are obtained for \( f_c = 60 \text{GHz} \) and \( W = 1 \text{GHz} \) (the signal duration is \( \tau_p = (1 + \beta)/W = 1.6 \text{ns} \) in free-space conditions. Root raised cosine (RRC) transmitted pulses centered at frequency \( f_c = 60 \text{GHz} \) and roll-off factor \( \beta = 0.6 \) are adopted, being compliant with the Federal Communications Commission (FCC) mask at 60 GHz [21]. A noise figure of \( N_{\text{ef}} = 4 \text{dB} \) and a fixed transmitted power of \( P_t = 10 \text{mW} \) are considered, if not otherwise indicated.

The performance is evaluated in terms of PEB averaged over \( N_{\text{cycle}} = 500 \) Monte Carlo iterations. For each cycle, a different 3D RX array orientation is generated. The antennas are spaced apart of \( d_{\text{ant}} = \lambda_L/2 \), where \( \lambda_L = c/f_L \) and
For all the configurations, and thus, it can be relaxed in order to guarantee an easy integration in portable devices.

In Fig. 4, the PEB results are reported as a function of the receiving antennas with \( N_{tx} \) fixed to 25. The same considerations drawn for Fig. 3 hold with the exception of those regarding the dependence on \( N_{rx} \). Indeed, in this case, a higher number of antennas translates in a higher number of collected measurements and thus, in an increased localization accuracy.

VI. CONCLUSION

In this paper, we have considered a new scenario where a single-anchor localization exploiting mm-wave massive arrays has been put forth for next 5G applications. The theoretical PEB has been evaluated for different beamforming strategies, i.e., classical vs. random beamforming. Moreover, phase quantization errors and arrays orientation have been taken into account in the analysis.

From numerical results, we can conclude that classical beamforming permits to achieve a better localization performance thanks to the capability of focusing the power towards a precise direction in space; nevertheless, random beamforming attains a sub-centimeter accuracy even when the number of antennas is not extremely massive. Finally, the impact of quantization errors can be considered negligible. Consequently, whenever the localization requirements are not too stringent, it is possible to relax the implementation constraints (i.e., adoption of switches instead of analog PSs) without severely degrading the localization performance.
