Abstract

Nuclear structural materials subjected to neutron irradiation accumulate dose-dependent, disperse defect clusters populations. Subsequent dislocation/defect interactions induce material mechanical property degradations, including hardening and embrittlement. Our goal in this work is to evaluate the effect of disperse defect clusters population on the effective dislocation mobility in ferritic Fe-Cr grains, using 3D dislocation dynamics simulations. The defect induced changes of the grain-scale mechanical response are evaluated using the recently proposed Defect-Induced Apparent Temperature (DIAT) shift concept. It is found that the DIAT shift associated with a given defect dispersion scales with the ductile to brittle transition temperature (DBTT) shift associated with exactly the same, observed defect population. The dose-dependent evolutions associated with broad irradiation temperature and straining temperature changes are investigated herein, for further exploration and validation of the DIAT shift concept.

Keywords: 3D dislocation dynamics simulation; DIAT shift; DBTT shift; temperature effect;

1. Introduction

Reactor Pressure Vessel (RPV) steels subjected to neutron irradiation accumulate dose-dependent defect cluster populations [1][2]. This effect significantly influences the lifetime and serviceability of nuclear power plants (NPP), through its impact on dislocation-mediated plastic deformation mechanisms. Namely mobile dislocations strongly interact with the radiation-induced loops, as observed in TEM [3][6] and predicted by various simulation methods [5][7]. More recently, the statistical evolutions of the screw dislocation populations in presence of the radiation induced defects has been evaluated using three dimensional dislocation dynamics simulations [9]. These investigations have shown that the influence of disperse defect populations on the effective dislocation mobility can be characterized by a scalar indicator called the Defect-Induced Apparent Temperature (DIAT) shift. Interestingly, the DIAT shift magnitude and the radiation-induced evolution of the Ductile-Brittle Transition Temperature (DBTT) shift can be associated with exactly the same defect dispersion. Our goal in this work is to investigate the DIAT shift sensitivity on the irradiation temperature and the straining temperature, in relation with the corresponding DBTT shift evolutions.

2. Model and method descriptions

2.1 Dislocation mobility rules and cross-slip algorithm

The 3D dislocation dynamics simulations are performed using TRIDIS code, whereby the dislocation lines are treated as discrete, orthogonal edge and screw segments [10]. In BCC materials (such as ferritic RPV steel), the edge dislocation segment velocity writes:

$$v_{edge} = \frac{\tau^* b}{B} \quad (1)$$

where τ^* is the effective resolved shear stress, b the magnitude of Burgers vector and B the viscous drag coefficient. Screw dislocation mobility however depends on the thermally activated generation of kink-pairs, as sketched in Fig. 1. The kinks subsequently glide away from each other, until the screw dislocation propagates to the next Peierls valley. Screw dislocation mobility associated with the thermally activated nucleation of kink pairs depends on the «kink-pair nucleation rate per unit length», which writes [11]:

$$J(\tau^*, T) = \frac{8\pi(\tau^*)^2}{\mu Bh} \exp\left(-\frac{\Delta H_0}{k_B T} \left[1 - \left(\frac{\tau^*}{\tau_0}\right)^p\right]^q\right) \quad (2)$$

where h is the Peierls valley width, μ is the shear modulus, k_B the Boltzmann's constant, T is the temperature, and ΔH_0 the kink-pair formation enthalpy. Parameters p and q characterize the shape of the thermal activation barrier with respect to τ^* variations, thus the term in the exponential bracket represents the total kink-pair formation enthalpy ΔG . Accounting for subsequent kink pair propagation at finite velocity allows expressing the screw dislocation velocity as:

$$v_{screw} = hJX' = hJ \frac{X_\infty L}{X_\infty + L} \quad (3)$$

where the last term in Eq. (3) represents the glide distance of the kink pair along a finite-length screw dislocation, before its annihilation with a kink pair of opposite sign. Quantity L is the dislocation length and X_∞ is the kink-pair propagation distance along an infinite-long screw dislocation.

The present simulations carried out herein are adapted to Fe-Cr grains, through the material dependent parameters as listed in Tab. 1. This kink-pair model ensures a progressive stress-velocity transition, with increasing straining temperature. The screw cross-slip mechanism is implemented using the stochastic procedure as described in [12]. It can be shown that the present DD calculations generate stress-strain evolutions compatible with Fe-Cr steels grains for all straining temperatures, within the ductile to brittle temperature range.

ΔH_0 (10^{-20} J)	τ_0 (MPa)	p	q	Viscous drag coefficient $B(10^{-5}$ Pa s)	Burgers vector $b(10^{-10}$ m)	Young modulus E (GPa)	Poisson ratio ν	Time step Δt (s)
4.86	358	0.5	1	34	2.54	210	0.3	10^{-10}

2.2 Simulation cases and DIAT shift concept

The simulation cell adopted in this work is a $1 \mu\text{m}^3$ sized cubical grain. The outer grain interfaces are impenetrable for dislocation segments, which allows for a realistic description of intra-granular stress (e.g. strain localization, for example) [13][15]. The initial dislocation sources belong to the $a/2 (1 0 1) \langle -1 -1 1 \rangle$ (associated with $a/2 (1 -1 0) \langle -1 -1 1 \rangle$ and $a/2 (0 1 1) \langle -1 -1 1 \rangle$ slip systems) slip system. Plastic deformation of the grain

is carried out under the strain rate controlled conditions ($\dot{\epsilon} = 100 \text{ s}^{-1}$), with a tensile load applied along the (100) uni-axial tension direction. The radiation induced defects (interstitial dislocation loops, mainly) are implemented in the form of a population of soft planar interfaces called facets, oriented normal to the (100) direction. The facet strength is calibrated based on the MD simulations, as explained in [15]. Detailed validation of this simplified dislocation/defect implementation has been presented elsewhere [16][17]. It is known that the defect dispersions are strongly influenced by the radiation condition. Therefore varying the defect number density N and the defect size D allow us for investigating the radiation temperature effect on the dislocation mobility evolutions.

At fixed straining temperature, the (screw) dislocation mobility is significantly affected (reduced) by the presence of the disperse defects. Such evolution can be evaluated quantitatively using the DIAT shift concept as explained in [9]. This idea is based on observation: the (screw) dislocation mobility is influenced by both the straining temperature and the dislocation/defect interactions. In other words, the addition of dispersed defects in a pristine grain or crystal yields exactly the same (global) effect as depressing the straining temperature by a certain, definite amount. This apparent straining temperature shift is defined as DIAT shift, which turns to closely reflect the DBTT shift evolutions obtained for a broad range of disperse defect population conditions (see [9][18]).

The Δ DIAT calculation procedure is briefly explained below. Firstly, the defect-free grain is strained at temperature T_0 to obtain the average, reference screw dislocation motion ($\bar{\tau}_0^*, \bar{v}_0$). Next, the irradiated grain is strained up to the same plastic strain level at the same temperature T_0 . Then the deviation of (τ_1^*, v_1) combinations from the ($\bar{\tau}_0^*, \bar{v}_0$) for each screw dislocation segment can be calculated as follows:

$$\frac{\bar{v}_0}{v_1} \left(\frac{\tau_1^*}{\bar{\tau}_0^*} \right)^{3/2} = \exp \left(\frac{\Delta G_1(\tau_1^*)}{2k_B T_1} - \frac{\Delta G_0(\bar{\tau}_0^*)}{2k_B T_0} \right) \quad (4)$$

It is important to note that the dislocation mobility rule is not changed for irradiated and un-irradiated grain and therefore, the evolution of the dislocation motion is entirely caused by

the implemented defect dispersions. A temperature shift ($T_0 - T_I$) is then obtained for each (screw) dislocation segment present in the simulated volume, yielding a single Δ DIAT value. In the next section, the radiation temperature effect and the straining temperature on the DIAT shift are examined and further discussed.

3. Results and discussions

3.1 Radiation temperature effect

The fracture response (i.e. the DBTT shift amplitude) of Fe-Cr materials strongly depends on the irradiation temperature, for a fixed irradiation dose condition. Changing the irradiation temperature indeed affects the defect dispersion characteristics, in terms of defect size D and defect number density N . For instance, the defect number density sharply decreases with increasing the irradiation temperature, whereas the loops sizes follow the opposite trend (see Tab. 2). The Δ DIAT associated various defect dispersion conditions are calculated as explained in section 2.2 (at $T_0 = 300$ K) and presented in Fig. 2.

T_{irra}	280°C	300°C	340°C	380°C
N (10^{18} m^{-3})	6000	4000	1600	700
D (nm)	10	12	15	20

Tab. 2 Defect number density and loop sizes of Fe-Cr at different irradiation temperatures, for irradiation doses up to 5dpa [19][21].

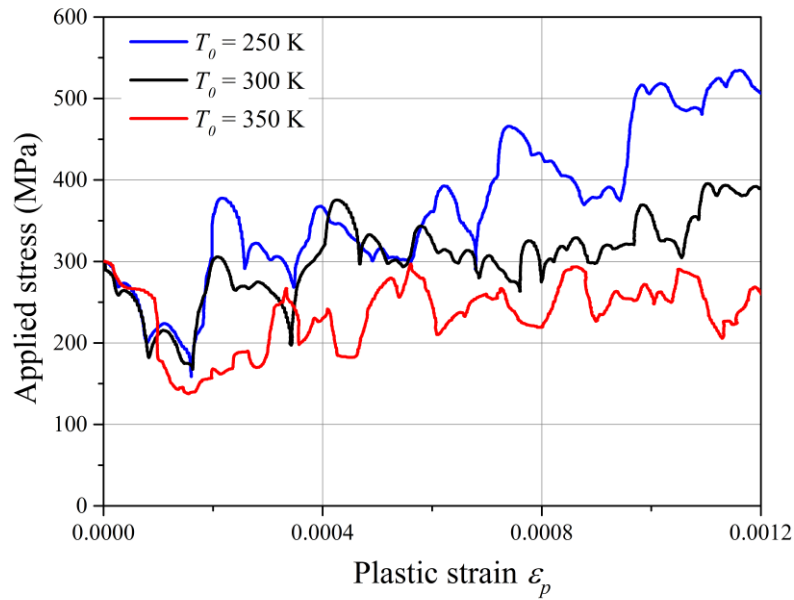

Fig. 2 DIAT shift evolution with the irradiation temperature in Fe-Cr grains.

The DIAT shift decreases with rising the irradiation temperature, up to $T_{irra} = 380^{\circ}\text{C}$. The corresponding $\Delta DBTT$ evolutions present exactly the same trend [2] (Figure 5), at least up to 1 dpa dose (Figure 6, [22]). In these conditions, it is found that the $\Delta DIAT$ magnitude and its evolutions reflect the evolutions of quantity \sqrt{ND} (see Tab. 2). The $\Delta DIAT/\Delta DBTT$ correlations are further explored and discussed in the next sections.

3.2 Straining temperature effect

Defect-free grains are simulated under three selected straining temperatures $T_0 = 250\text{K}$, 300K and 350K (in DBT range). The corresponding stress-strain curves are presented in Fig. 3(a), showing a pronounced applied stress amplitude decreases with increasing temperature. The corresponding dislocation density evolutions are shown in Fig. 3(b): the total dislocation density linearly augments with the accumulation of plastic strain. The

dislocation accumulation rate increases with straining temperature. For instance, the dislocation density at $\varepsilon_p = 0.0012$ with $T_0 = 350\text{K}$ is almost 2 times the value achieved at $T_0 = 250\text{K}$. This means that higher straining temperature induces faster dislocation multiplication rate, thus associated with increased dislocation activity. The present results are in good agreements with experimental observations [23], DD [24] and FEM [25] simulation results.

(a)

(b)

Fig. 3 Plastic strain spreading effect at different temperatures. (a) Stress-stain response. (b) Dislocation density versus plastic strain.

At each fixed straining temperature, we then introduce various defect dispersions into the grains, with a view to investigate the corresponding dislocation mobility evolutions, focusing on $D = 15 \text{ nm}$ loop size (corresponding to the radiation temperature around 300°C) and defect number density $N = 1000\sim 5000 \times 10^{18} \text{ m}^{-3}$ (corresponding to the dose in the range of 1~4 dpa) case. The ΔDIAT evolutions obtained with different straining temperatures are shown in Fig. 4. At $T_0 = 250\text{K}$, the ΔDIAT magnitude almost linearly increases with respect to the defect number density. In the other 2 cases, the ΔDIAT increases from $N = 1000 \times 10^{18} \text{ m}^{-3}$ to $N = 3000 \times 10^{18} \text{ m}^{-3}$ and then is saturates around 80K and 90K, respectively. For a fixed defect number density N , the ΔDIAT magnitude increases with the straining temperature, especially for $N > 1000 \times 10^{18} \text{ m}^{-3}$.

Fig. 4 ΔDIAT as functions of the defect number density N , for different straining temperatures.

Interestingly, the ΔDIAT evolutions with straining temperature closely reflect the corresponding fracture toughness response evolutions as shown in Fig. 5(a). Namely the impact energy shift increases with the testing temperature ($T_0 > T_0'$). This evolution is consistent with enhanced multiplication and propagation of dislocation populations near the fracture surface of the tested specimens. This effect directly relates to rate of dislocation/defect interaction as evaluated during the DD simulations. In the $N = 3000 \times 10^{18} \text{ m}^{-3}$ case for example, the dislocation/defect interaction count at $T_0 = 350\text{K}$ is almost four times higher than at $T_0 = 250\text{K}$ (for a fixed $\epsilon_p = 10^{-3}$). The (screw) dislocation population activity is then more pronounced at higher straining temperature, where the presence of defect dispersion has a larger relative impact, in terms of dislocation mobility, as shown in Fig. 5(b). This situation explains that $(T_0 - T_I) > (T_0' - T_I')$ for $T_0 > T_0'$ and hence, a DIAT shift increases with the straining temperature.

Fig. 5 Straining temperature effect. (a) Typical resilience curves obtained in un-irradiated and irradiated materials, with $T_0 > T_0'$. (b) Screw dislocation velocity versus the effective resolved shear stress, for different straining temperatures. Subscript 0 represents the dislocation motion in unirradiated grain and subscript 1 indicates the irradiated case.

We have shown that the influence of a given defect dispersion (characterized by N and D) on dislocation mobility increases with the straining temperature, as does the ductile to brittle transition temperature shift associated with exactly the same N and D case. This comparison indicates that the DIAT shift concept can potentially predict the dose-dependent DBTT evolutions associated with a broad range of irradiation conditions.

Conclusion

Plastic deformation of the Fe-Cr cubic grains has been simulated using a 3D dislocation dynamics modelling approach, including thermally activated dislocation mobility rules. The effect of disperse defect populations on the effective (screw) dislocation mobility has been evaluated using the statistical, DIAT shift indicator. At fixed straining temperature, the

Δ DIAT magnitude decreases with the irradiation temperature, as does the Δ DBTT trend associated with the exactly the same irradiation temperature evolution. For a fixed irradiation temperature (i.e. for a fixed disperse defect population N and D case), the Δ DIAT level increases with the straining temperature, in agreement with the corresponding resilience test results (Δ DBTT), due to exactly the same straining temperature evolution. The results presented in this paper show that the DIAT shift concept can potentially predict the dose-dependent DBTT shift evolutions associated with a broad range of irradiation and testing conditions.
