ABSTRACT

The vibration of rods is of prime importance to estimate their wearing due to the frictions with grids' elements. To predict this wearing, the forces exerted on the rods need to be identified and quantified. Pressure fluctuations are explored using an instrumented rod centred within a 5x5 rods bundle. Two configurations of spacer-grids are used: with and without mixing vanes respectively noted WMV and NMV. The position of the measurement point is rotated over 360° and its distance from the grids is varied from 0.5D_h to 20D_h. The results show the non-homogeneity of the azimuthal distribution of the pressure fluctuations in the near wake of the spacer-grids for both configurations. The return to a homogeneous azimuthal distribution of the pressure fluctuations is faster without mixing vanes than with mixing vanes. The intensities of the pressure fluctuations are (in average) higher for WMV than for NMV: higher by 13% and 136% respectively at distances 0.5D_h and 20D_h from the grids. Power law approximations show decreases of $\langle P'_{rms} \rangle_\theta$ like $(y/D_h)^{-0.46}$ and $(y/D_h)^{-0.68}$ respectively for the configurations WMV and NMV. The profiles of mean velocity and velocity fluctuations are explored around the instrumented rod using LDV. Results show oscillation of the profiles and a damping with the distance from the grids. Power law approximations show decreases of $\langle v'_{rms} \rangle_{p_{sq}}/V_{flow}$ like $(y/D_h)^{-0.38}$ and $(y/D_h)^{-0.46}$ respectively for WMV and NMV. Between 2D_h and 15D_h, the dimensionless ratio of “pressure fluctuations to velocity fluctuations” $\langle P'_{rms} \rangle_\theta / \frac{1}{2} \rho \langle v'^2_{rms} \rangle_{p_{sq}}$ is found to increase by 70% and 100% respectively for the configurations NMV and WMV. This increase demonstrated by the combination of pressure and velocity measurements further reveals the complexity of the turbulent flow in the wake of spacer-grids.

1 INTRODUCTION

The vibration of rods is of prime importance to estimate their wearing due to frictions with grids' elements. To predict this wearing, the forces exerted on the rods need to be identified and quantified. To this aim, an experimental study tailored for the validation of CFD simulations is performed with the support of the “FUEL ASSEMBLY Project” (AREVA, CEA, EDF). In addition, it is expected that the combination of such refined experiments and CFD simulations will support the characterisation of the hydraulic performance of the grids.

Previous works addressing the flows within rods bundle in the near wake of spacer-grids include research using PWR spacer-grids, e.g. [1], and analytical spacer-grids, e.g. [2, 3, 4, 5]. Here the experiments are performed with analytical spacer-grids.

The experiments are performed with the rig CALIFS which is a water experimental rig (low-pressure, 20°C) dedicated to the study of turbulent flows within rods bundle. The experiments are performed using

Abstract No: 188 oral presentation

Paper No.:

a 5x5 rods bundle. Two sets of different grids, with and without mixing vanes, are used to mount the rods bundle.

This manuscript focuses on Reynolds number 66000 where refined pressure and velocity measurements are performed. The experimental rig and measurements are described before discussing results.

2 EXPERIMENTAL RIG AND MEASUREMENTS

2.1 DESCRIPTION OF THE EXPERIMENTAL RIG

Fig. 1 (a) 3D illustration of the rig CALIFS 5x5; (b) photo of the test section with the 5x5 rods bundle and grid without mixing vanes; (c) schematic of flow cross-section with the rods bundle. The central (blue) square shows the perimeter P_{sq} and the central segments (light blue) the LDV measurements lines of $2D_h$ length. The reference position 0° and 90° for the pressure measurements are also indicated close to the central rod; (d) schematic with the positions of the grids along the test-section.

CALIFS 5x5 is a water rig working within the ranges 0-400m³/h, 10°-70°C, 0-10bar. Fig. 1a gives a 3D schematic of CALIFS 5x5 and Fig. 1b shows a photo of the test section. The length of the test section is about 2.5m. The flow cross section is a square of 184mm side. A 5x5 rods bundle, using rods of diameter

Abstract No: 188 oral presentation

Paper No.:

$D_{rod}=26.9\text{mm}$, is placed within the test section using four spacer-grids. The hydraulic diameter, noted D_h , is 27.7mm and is used as the reference length scale.

The geometry of the test section and the distribution of these grids are illustrated in Fig. 1c and Fig. 1d. The grids number 1 and 4 are without mixing vanes. Both grids 2 and 3 are without or with mixing vanes for the cases respectively noted NMV and WMV for No Mixing Vanes and With Mixing Vanes.

Fig. 2 illustrates the grids with and without mixing vanes. The grids are made with 1.2mm thick plates of stainless steel 304L. The height of the plates is 93mm they are assembled perpendicularly to design a mesh with 25 cells. Within each cell, the rods are sustained radially using dimples and springs-blades. The dimples are made of TEFLON and the springs-blades are made with 1mm thick blades of stainless steel 301 T4.

Fig. 2 (a) top row, schematics of the grids without mixing vanes; (b) bottom row, schematics of the grid with mixing vanes

The origin of the coordinates is set as the centre of the central rod at the exit of the grids. y is the vertical direction and x and z are horizontal as illustrated in Fig. 1c.

Experiments are performed with a flow rate velocity, noted V_{flow} , of 2.4m/s and a flow temperature about 20°C. The Reynolds number, Re_{D_h} , of the experiments is then about 66000.

2.2 PRESSURE MEASUREMENTS

Pressure drops and unsteady local pressure measurements are performed. Local pressure measurements are realised by instrumenting the central rod of the 5x5 rods bundle. The distribution of pressure around the rod circumference is obtained by turning the instrumented rod: increment of 10° are performed over 360°. As illustrated in Fig. 1c, the angular positions, noted θ , are referred clockwise. The 0° and 90° correspond respectively to the measurement point positions ($z/D_h=-0.97$, $x/D_h=0$) and ($z/D_h=0$, $x/D_h=0.97$). The pressure distribution is measured at various longitudinal positions from the grid by translating the instrumented rod: $0.5D_h$, $1D_h$, $2D_h$, $3D_h$, $4D_h$, $5D_h$, $10D_h$, $15D_h$ and $20D_h$.

Two pressure devices¹ are used. For the first campaign (grid without mixing vanes, NMV) a pressure sensors is mounted on a cavity within the rod with a 2 mm diameter pipe linking the cavity to the flow [6]. For the measurements' accuracy, the whole pressure device (including sensor, cavity and 2mm pipe) is calibrated. For the second campaign (grids with mixing vanes, WMV), a smaller pressure sensor of diameter 1.9mm is mounted flush to the rod so as to be in contact with the flow. It can be noted that the diameter of the last sensor (or the hole) is about 44 times smaller than the rod's perimeter. Each local pressure measurement is performed during 20s at 1600Hz using a 400Hz low pass analogue filter. The uncertainties of the vertical and angular positions of the measurements points are respectively $\pm 1\text{mm}$ and $\pm 1^\circ$.

2.3 VELOCITY MEASUREMENTS

The velocity measurements are performed using LDV (Laser Doppler Velocimetry) and translating the measurement point. The first point is set at 1.33mm from the wall and consecutive points are 1.33mm spaced. The largest length of the measurement volume is about 0.94mm. The LDV acquisition rate depends on the rate of the particles (4 μm NYLON beads) crossing the measurement volume. The LDV statistics rely on 10 000 valid events for each measurements points. The uncertainty on the position of the measurement volume is about $\pm 0.5\text{mm}$ whilst the displacement uncertainty is of the order of 0.01mm. On Fig. 1c, the light blue lines (combined with the blue square) show the segments on which the LDV measurements are performed and discussed in this manuscript. These segments correspond to $x/D_h = \pm 0.54$ for $-1 \leq z/D_h \leq 1$ and $z/D_h = \pm 0.54$ for $-1 \leq x/D_h \leq 1$.

3 RESULTS AND DISCUSSIONS

The Fig. 3 gives the azimuthal distributions of the root mean square (rms) of the pressure fluctuations, noted P'_{rms} , measured for the configurations with and without mixing vanes at different distances from the grids.

For $y/D_h \geq 1$, P'_{rms} is larger for the configuration with mixing vanes than for the configuration without. Moreover, for $y/D_h \geq 5$ the pressure fluctuations are about 2 times higher for the configuration WMV than for NMV. At the vicinity of the grid, i.e. $y/D_h \leq 2$, the distributions of P'_{rms} are non-homogeneous with θ . Extrema of pressure fluctuations can be attributed to the effect of the dimples, spring-blades, and mixing vanes. For $y/D_h \geq 2$, the pressure fluctuations of the flow evolve faster toward a quasi-homogeneous distribution for the configuration without mixing vanes than for the configuration with mixing vanes. In fact, the distribution of the pressure fluctuations is quasi-homogeneous for $y/D_h \geq 5$ for the configuration without mixing vanes whilst such homogeneity can still be discussed at $y/D_h = 20$ for the configuration with mixing vanes.

The average over θ of P'_{rms} , noted $\langle P'_{rms} \rangle_\theta$, decreases with y/D_h . Fig. 4 gives $\langle P'_{rms} \rangle_\theta$ versus y/D_h and highlights two power law trends $\sim (y/D_h)^{-0.46}$ and $\sim (y/D_h)^{-0.68}$ respectively for the configurations WMV and NMV. Between $y/D_h = 0.5$ and $y/D_h = 20$, so within $20D_h$, the values of $\langle P'_{rms} \rangle_\theta$ are divided by about 10 and 5 respectively for the NMV and WMV configurations.

To investigate the frequency domain of the pressure fluctuations the energy spectra of the temporal signal of the pressure fluctuations, noted $\mathcal{E}(k^*)$, where $k^* = fD_h/V_{flow}$, is computed and made dimensionless using the total energy $\mathcal{E}_{total}$ so as $\sum \mathcal{E}(k^*)dk^*/\mathcal{E}_{total} = 1$.

Fig. 5 provides the dimensionless energy spectra averaged over θ , $\langle \mathcal{E}(k^*) \rangle_\theta / \mathcal{E}_{total}$, for the distances from the grid $0.5D_h$, $1D_h$, $2D_h$, $3D_h$, $4D_h$, $5D_h$, $10D_h$, $15D_h$, $20D_h$ and the two configurations NMW and WMV. For all distances, the WMV configuration shows more energy at large scales, i.e. $k^* \leq 0.5$, than the NMV configuration. At $0.5D_h$ both energy spectra present a similar peak around $k^* = 0.8$. In addition, for the configuration with mixing vanes a damping of the intensity of the peak around $k^* = 0.8$ is observed whilst for the configuration without mixing vanes this peak persists from $0.5D_h$ to $20D_h$.

¹ Both pressure transducers are amenable to perform at frequencies higher than 10kHz.

Abstract No: 188 oral presentation

Paper No.:

Fig. 5 azimuthal average of the reduced energy spectra of the pressure fluctuations $\langle \mathcal{E}(k^*) \rangle_\theta / \mathcal{E}_{total}$ for the cases of grids with mixing vanes (WMV) and without mixing vanes (NMV) for different vertical distances from the grids, i.e. 0.5D_h, 1D_h, 2D_h, 3D_h, 4D_h, 5D_h, 10D_h, 15D_h and 20D_h.

The average velocity (over time), noted $\bar{v}$, is explored around the central instrumented rod. This measurement region is illustrated by the light blue segments on Fig. 1c.

The Fig. 6 shows the $\bar{v}/V_{flow}$ dimensionless velocity profiles for $x/D_h = \pm 0.54$, $-1 \leq z/D_h \leq 1$ and $z/D_h = \pm 0.54$, $-1 \leq x/D_h \leq 1$ and y/D_h distances from the grids of 2, 3, 4, 5, 10 and 15.

The configuration without mixing vanes presents oscillations of the velocity profiles at $y/D_h = 2$. These oscillations are attributed to the upstream presence of the dimples and spring-blades. With the increase of y/D_h , the number and the amplitude of these oscillations tend to diminish. Although, the persistence of a main oscillation can be observed.

The configuration with mixing vanes also present some oscillations. Although they tend to be of weaker amplitude than for the configuration without mixing vanes. The number and amplitude of these oscillations decrease with y/D_h . In addition, apart from $x/D_h = 0.54$, the persistence of a main oscillation is much less pronounced for the case with mixing vanes than for the case without mixing vanes at $y/D_h = 15$.

To complement the velocity profiles, the root mean square of the velocity fluctuations, noted v'_{rms} , is quantified. The Fig. 7 gives the dimensionless profiles v'_{rms}/V_{flow} for $x/D_h = \pm 0.54$, $z/D_h = \pm 0.54$, and distances y/D_h from the grids equals to 2, 3, 4, 5, 10 and 15.

Both configurations with and without mixing vanes show oscillations of v'_{rms}/V_{flow} in agreement with the oscillations observed for $\bar{v}/V_{flow}$. With the increase of the distance from the grid the amplitude of the oscillations and the intensity of v'_{rms}/V_{flow} reduce. The persistence of a main oscillation is also observed.

Fig. 6 velocity profiles $\bar{v}/V_{flow}$ for $x/D_h = -0.54$, $x/D_h = +0.54$, $z/D_h = -0.54$, $z/D_h = +0.54$ (columns from left to right) and y/D_h equals to 2, 3, 4, 5, 10 and 15 (rows from top to bottom).

Fig. 7 profiles of the root mean square of velocity fluctuations velocity v'_{rms}/V_{flow} for $x/D_h = -0.54$, $x/D_h = +0.54$, $z/D_h = -0.54$, $z/D_h = +0.54$ (columns from left to right) and y/D_h equals to 2, 3, 4, 5, 10 and 15 (rows from top to bottom).

From $y/D_h = 2$ to $y/D_h = 15$, the intensity of turbulent fluctuations (v'_{rms}/V_{flow}) is decreasing from about 0.2 to about 0.08. The Fig. 8 gives the variations $\langle v'_{rms} \rangle_{P_{sq}}/V_{flow}$ versus y/D_h . $\langle v'_{rms} \rangle_{P_{sq}}$ is the average of v'_{rms} along P_{sq} which is the measurement perimeter close to the instrumented rod as illustrated by the blue square on Fig. 1c. Fig. 8 also gives an approximation with power laws and shows trends $(y/D_h)^{-0.38}$ and $(y/D_h)^{-0.46}$ respectively for the configurations with and without mixing vanes.

Fig. 8 $\langle v'_{rms} \rangle_{\mathcal{P}_{sq}} / V_{flow}$ for the cases of grids with mixing vanes (WMV) and without mixing vanes (NMV) versus the vertical distance y/D_h from the grids. Grey lines indicate power law trends.

The decrease with y/D_h of velocity fluctuations is then faster for the configuration without mixing vanes than for the one with mixing vanes. The contrary was observed for pressure fluctuations.

It is interesting to compare the decrease of pressure fluctuations with the decrease of velocity fluctuations versus y/D_h . The dimensionless ratio $\langle P'_{rms} \rangle_{\theta} / \frac{1}{2} \rho \langle v'^2_{rms} \rangle_{\mathcal{P}_{sq}}$ compares these values. If the pressure fluctuations were strictly related to the velocity fluctuations, one would expect this dimensionless ratio to be about a constant.

Fig. 9 gives $\langle P'_{rms} \rangle_{\theta} / \frac{1}{2} \rho \langle v'^2_{rms} \rangle_{\mathcal{P}_{sq}}$ versus y/D_h . The dimensionless ratio $\langle P'_{rms} \rangle_{\theta} / \frac{1}{2} \rho \langle v'^2_{rms} \rangle_{\mathcal{P}_{sq}}$ is not constant with y/D_h . Significant increases are observed between $y/D_h = 2$ and $y/D_h = 15$. The increases are about 70% and 100%, respectively for the configurations without and with mixing vanes.

Fig. 9 $\langle P'_{rms} \rangle_{\theta} / \frac{1}{2} \rho \langle v'^2_{rms} \rangle_{\mathcal{P}_{sq}}$ for the cases of grids with mixing vanes (WMV) and without mixing vanes (NMV) versus the vertical distance y/D_h from the grids.

Such increases of the ratio $\langle P'_{rms} \rangle_{\theta} / \frac{1}{2} \rho \langle v'^2_{rms} \rangle_{\mathcal{P}_{sq}}$ can be due to the persistence of coherent structures responsible for the main contribution to the pressure fluctuations whilst the non-coherent part of the turbulence generated behind the grids damps more rapidly with y/D_h . $\langle P'_{rms} \rangle_{\theta}$ would be sustained by these persistent pressure structures that can be related to the presence of a peak in the pressure spectra

of Fig. 5. $\frac{1}{2}\rho\langle v_{rms}'^2 \rangle_{P_{sq}}$ will be more affected by the damping of the turbulence downstream the grids. To the knowledge of the authors, such quantification and observation are new results. It provides a new insight about the physic of the flow and highlights the possibility to get persisting pressure structures whilst the velocity fluctuations are more affected by the damping of the turbulence downstream the grids with and without mixing vanes.

4 CONCLUSION

Pressure fluctuations are explored using an instrumented rod. The orientation of the measurement point and the distance from the grids are varied to explore the flow region surrounding the instrumented rod between $0.5D_h$ and $20D_h$ downstream the grids. The azimuthal distribution of the pressure fluctuations is then explored for different distances. This shows the non-homogeneity of the pressure fluctuations for both configurations without and with the mixing vanes. It is observed that the return to a homogeneous azimuthal distribution of the pressure fluctuations is faster for the configuration without the mixing vanes than for the configuration with the mixing vanes. Moreover, the intensities of the pressure fluctuations are (in average) higher for the configuration with mixing vanes than for the one without mixing vanes: higher by 13% and 136% respectively at distances $0.5D_h$ and $20D_h$ from the grids. Power law approximations shows decreases of $\langle P'_{rms} \rangle_\theta$ like $\sim (y/D_h)^{-0.46}$ and $\sim (y/D_h)^{-0.68}$ respectively for the configurations with and without mixing vanes.

The profiles of mean velocity and velocity fluctuations are explored around the instrumented rod using LDV. The results show oscillations of the profiles and a damping with the increases of the distance from the grids. Power law approximations show decreases of $\langle P'_{rms} \rangle_\theta$ like $\sim (y/D_h)^{-0.38}$ and $\sim (y/D_h)^{-0.46}$ respectively for the configurations with and without the mixing vanes.

To study the persistence of the pressure fluctuations compared to the velocity fluctuations, $\langle P'_{rms} \rangle_\theta / \frac{1}{2}\rho\langle v_{rms}'^2 \rangle_{P_{sq}}$ is plotted versus y/D_h . It is shown that this ratio is not constant with significant increases between $2D_h$ and $15D_h$: 70% and 100% respectively for the configuration without and with mixing vanes. To the knowledge of the authors, this new and original result highlights the complexity of the pressure and turbulent structures in the wake of the grids with and without the mixing vanes.
