HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

Figure S1. Scheme of solid samples sliced for LIBS-micro probe characterization.

(Left) Scheme of through-diffusion cell (diffusion gradient along X-axis).
(Right) Scheme of C1 and C2 solid samples sliced after diffusion.

A post-mortem characterization of the clay rock was performed after diffusion. To this aim, two rock samples were sliced. Eu mapping was measured by LIBS-micro probe technique. Several mapping were performed on center of C1 and C2 slices. Typical dimensions of mapping were dX×dZ~10×1 mm² as shown in Fig. S1.

Adsorption kinetics of $^{152}$Eu-EDTA and $^{14}$C-EDTA on COx clay rock

Adsorption kinetics for $^{152}$Eu in presence of EDTA and $^{14}$C-EDTA was measured on COx clay rock up to 14 days. A rough estimation was performed assuming an exponential decay of concentration in solution. The kinetic rate was then extrapolated by linear regression on ln[(C(t)-C∞)/(C₀-C∞)] (Figure S2, top). The corresponding rate, $k_{\text{EXP}} = 1.71 \times 10^{-6}$ s⁻¹, was used to model run C. All kinetics data are gathered in Figure S2 (bottom) and were in the range $[10^{-6} - 2 \times 10^{-5}]$ s⁻¹.
**Effect of kinetics on through-diffusion modelling**

The effect of slow reversible adsorption kinetics was modelled using semi-analytical solutions provided for through-diffusion cells by Moridis (1998). The adsorption rate for run C was supposed equal to the value measured by batch experiments: $k = 1.71 \times 10^{-6}$ s$^{-1}$. The best fit was obtained with values $D_c = 1.74 \times 10^{-12}$ m$^2$.s$^{-1}$ and $K_d = 2.08$ L.kg$^{-1}$ is presented in figure S3. This modelling highlights two results. Firstly, an early rise of the downstream flux before 70 days may be explained by slow adsorption. Secondly, such adsorption kinetic fail to explain the main difference between $R_d$ measured in batch experiments and $K_d$ adjusted from diffusion experiments.
Figure S3. Modelling of downstream flux (top) and upstream concentration (bottom) with two models: MIED and MORI respectively without and with taking into account adsorption kinetics. Adjusted parameters are \((D_e, K_d) = (1.5 \times 10^{-12}, 1.8)\) and \((1.7 \times 10^{-12} \text{ m}^2 \text{s}^{-1}, 2.1 \text{ L kg}^{-1})\) for MIED and MORI respectively. Dark curves represent effect of adsorption rates five times higher or five times lower than the experimental value: \(k = 1.71 \times 10^6 \text{ s}^{-1}\).
