RAFM steels such as Eurofer-97 and Eurofer-ODS are potential structural materials for future fusion reactors. In order to study their resistance to the high energy neutrons they will be subjected to in this context, we have irradiated these materials in single-, dual- and triple-beam mode to 26 dpa at 400 °C. In single-beam mode (Fe ions only), both materials resist swelling but dislocation loops form. For dual- (Fe and He ions) and triple-beam (Fe, He and H) modes, the same dislocation loop microstructure is observed as for the single-beam mode, but small cavities form, aided by the presence of gases. Despite the formation of cavities, swelling is very low for the present conditions. The influence of ODS particles on swelling is briefly discussed.

## 1. Introduction

Reduced-activation ferritic-martensitic (RAFM) steels are considered to be the most promising materials for a use as structural materials in future fusion reactors [1,2], thanks to their low activation by neutron irradiation, their low swelling under irradiation and their good thermo-mechanical properties [1]. However, some questions remain concerning their resistance to swelling in the presence of helium and hydrogen produced by transmutation reactions due to 14 MeV neutron irradiation [3]. High temperature

helium embrittlement could also potentially be a problem [4–7]. Before a facility like IFMIF [8] that will produce high fluxes of 14 MeV neutrons is available, one of the best ways to study the combined effects of irradiation and simultaneous gas production is a multi-beam ion-irradiation facility like JANNUS Saclay [9,10]. In this paper we present results concerning the microstructure of EUROFER-97 and EUROFER-ODS (0.5wt.%Y<sub>2</sub>O<sub>3</sub>) steels after ion-irradiation.

The response of these materials to irradiation has been studied several times, however, to our knowledge, charged-particle multi-beam irradiations of these materials have not yet been reported. Hereafter, we present a short review of previous results concerning the irradiation of EUROFER-97 and EUROFER-ODS, with emphasis on microstructural characterizations.

EUROFER-97 has been studied extensively following neutron irradiations in HFR Petten and BOR-60. Klimenkov et al. [11] irradiated EUROFER-97 to 16.3 dpa in HFR at temperatures from 250 °C to 450 °C. They showed that the dislocation loop density peaks at

$4 \times 10^{21} \text{ m}^{-3}$  for a temperature of 300 °C and that the average loop diameter goes from 7 nm at 250 °C to 35 nm at 350 °C then back down to 10 nm at 450 °C. For all temperatures, the authors report that all dislocations loops had  $a_0/2\langle 111 \rangle$  type Burgers vectors. At 350 and 400 °C, a small density of cavities was detected. Due to the very low boron content of EUROFER-97, the total helium concentration is estimated as <10 appm for these irradiations.

EUROFER-97 was also irradiated in BOR-60 to 15 and 32 dpa, but for only one temperature: 330 °C (final He content well below 10 appm) [12]. Interstitial clusters/dislocation loops are reported to be present at 15 dpa with a mean size of 3.4 nm and a density of  $1.4 \times 10^{22} \text{ m}^{-3}$  and at 32 dpa with a mean size of 4.8 nm and a density of  $1.7 \times 10^{22} \text{ m}^{-3}$ . Small cavities are detected for both conditions. At 15 dpa, their mean size is 2.6 nm and their density is  $3.6 \times 10^{20} \text{ m}^{-3}$ . At 32 dpa, their mean size is 1.6 nm and their density is  $2.3 \times 10^{21} \text{ m}^{-3}$ .

The higher loop density obtained by Weiss et al. [12] at 15 dpa in BOR-60 compared to Klimenkov et al. [11] at similar temperatures can be explained by the fact that the later authors only counted defects clearly resolvable as dislocation loops.

Boron-doping has also been used to study the combined effects of neutron irradiation and helium production. In HFR [6,13], concentrations of ~80 appm He, ~415 appm He and ~5800 appm He were obtained for EUROFER-97 melted with various amounts of boron and irradiated to 16.3 dpa. Irradiation temperature went from 250 to 450 °C. Dislocation loops,  $\alpha'$ -precipitates and helium bubbles were observed by TEM after irradiation. For all specimens, He bubble size increases with irradiation temperature. For helium concentrations of 82 appm and 412 appm, it is shown that no cavities formed after irradiation at 250 °C (except at boron containing precipitates), randomly distributed cavities formed at 350 °C and preferential nucleation of smaller cavities on dislocations and grain boundaries occurred at 450 °C [6]. The swelling was maximal at a temperature of 350 °C at around 0.6%. Note that the use of boron presents some artifacts: first of all, in the 83 ppm  $^{10}\text{B}$ /~415 appm He sample, all B is transmuted in to He by 1 dpa. For other irradiations, some boron is still present at 16.3 dpa, and boron inclusions as well as (Cr,Fe)B and B(C,N) precipitates formed. This later feature means that the helium is produced heterogeneously to some extent. After irradiation to 250 °C, the presence of nanometer sized bubbles localized around boron containing precipitates was observed in a sample that otherwise did not contain bubbles [6]. On the other hand for an irradiation temperature of 250 °C and for a helium content of 412 appm the presence of nearly homogeneously distributed helium bubbles were found [13]. Comparison of these results with the findings in Ref. [6] indicates a non-homogeneous distribution of boron in the investigated RAFM steel. The present experiments by dual-beam ion irradiation may enable us to get more insight on the importance of such artifacts.

Small-angle neutron scattering (SANS) experiments have also been done on EUROFER-97 irradiated in HFR Petten up to doses of 2.5, 8.4, and 16.5 dpa at temperatures 250 and 300 °C (without boron). SANS experiments show that microvoids and  $\alpha'$  precipitates are present after irradiation, the  $\alpha'$  precipitates becoming dominant at 16.5 dpa. Between 2.4 and 8.9 dpa, the volume fraction of microvoids increases by a factor of nearly 2 while the average size of microvoids remains nearly unchanged [14].

Eurofer-97 has also been irradiated within STIP-II and STIP-III [15,16]. For STIP-II, EUROFER-97 samples irradiated with protons to 20.4 dpa/1795 appm He at a mean temperature of 309 °C contained very small cavities with sizes between 1.0 and 1.5 nm as well as dislocation loops (resolvable loops + black dots) with a density of  $4.3 \times 10^{22} \text{ m}^{-3}$  and average diameter of 6.1 nm. At 20.4 dpa/1795 appm He and 357 °C, the average cavity diameter was 2.5 nm and the density was  $4.4 \times 10^{23} \text{ m}^{-3}$ . The dislocation loop density

was  $3.1 \times 10^{22} \text{ m}^{-3}$  with an average diameter of 7.2 nm. Note however that the temperature varies greatly during such experiments, for example the specimen irradiated at a mean temperature of 357 °C suffered excursions to 309 and 406 °C [16]. Furthermore, for these spallation target irradiations, specimens are irradiated with protons and neutrons simultaneously. This makes the interpretation of results difficult.

Eurofer-ODS has also been studied after irradiation, usually by tomographic atom probe (TAP), in order to obtain data on nanoparticles enriched in yttrium and oxygen [17,18]. In Eurofer-ODS (0.3wt.% $\text{Y}_2\text{O}_3$ ) Williams et al. [17] did not detect any variation of particle size distribution and in the particle composition after Fe ion irradiations to 2 dpa at 400 °C. However, Rogozhkin et al. [18,19] found an increase of the particle density after irradiation and a loss of vanadium in particles in Eurofer-ODS (0.5wt.% $\text{Y}_2\text{O}_3$ ) irradiated to 32 dpa at 330 °C. The same team irradiated TAP needles of Eurofer-ODS with Fe ions at room temperature to three doses: 3.2, 10.2 and 13.2 dpa [19]. Pre-existing particles of Y, O, N and V were still visible with the same size and density after irradiation, but there was practically no more N and V in them. TEM characterization of irradiated Eurofer-ODS containing 0.5wt.%  $\text{Y}_2\text{O}_3$  is missing for the moment.

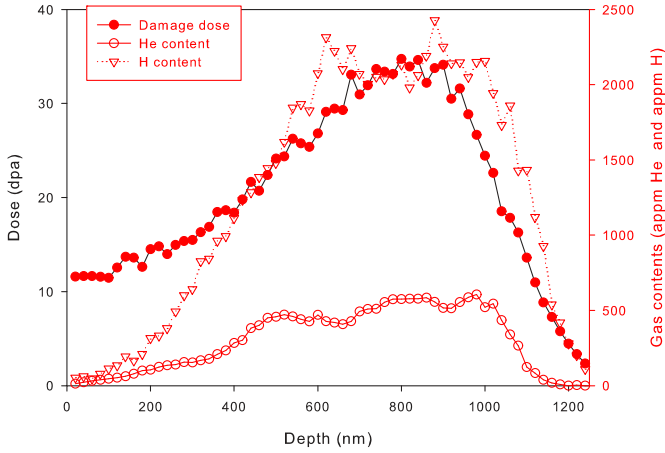

## 2. Experimental procedure

EUROFER 97 samples are from heat E83697 produced by Böhler Austria GmbH. Final heat treatment is a normalisation at 980 °C for 30 min plus tempering at 760 °C for 90 min followed by air cooling. EUROFER-ODS samples are from heat HXN 958/1, produced at Plansee by mechanical alloying of EUROFER powder with 0.5% yttria. After consolidation by hot isostatic pressing, the bar was normalized at 1100 °C for 30 min followed by an air/water quench and then tempered at 750 °C for 2 h. Final compositions are indicated in Table 1. For both materials, 1 mm thick slices were cut out and then polished mechanically to ~90  $\mu\text{m}$ , and 3 mm discs were finally punched out from the slices. Before irradiation, the discs were electro-polished for a few seconds in a Struers Tenupol 5 device with a 10% perchloric acid-20% 2-butoxyethanol-70% ethanol electrolyte, at room temperature and a voltage of 49 V in order to remove damage due to mechanical polishing.

The irradiations were performed in the triple-beam ion facility at JANNUS Saclay [9] in single- (3 MeV  $\text{Fe}^{3+}$ ), dual- (3 MeV  $\text{Fe}^{3+}$  and 1.2 MeV  $\text{He}^+$ ) and triple-beam (3 MeV  $\text{Fe}^{3+}$ , 1.2 MeV  $\text{He}^+$  and 600 keV  $\text{H}^+$ ) modes. All three irradiations were done at  $400 \pm 10$  °C. The sample temperature during irradiation was controlled by thermocouples and an FLIR infrared camera.  $\text{He}^+$  and  $\text{H}^+$  ions were

**Fig. 1.** Damage and implanted gas content profiles for the triple-beam irradiation to 27 dpa/440 appm He/2000 appm H calculated by SRIM [21] calculations.

implanted using energy degraders [10] made of thin aluminium foils. Periodic beam current measurements were performed with a system made up of three groups of seven Faraday cups, in order to calculate ion fluxes and fluences. All three beams were raster-scanned.

All damage levels and gas implantation rates were calculated using SRIM-2008 [21] ( $E_d = 40$  eV and Kinchin and Pease calculation, for a good comparison with neutron irradiation experiments [22]). The damage and gas implantation profiles for the triple-beam irradiation are presented in Fig. 1. Gas implantation profiles were calculated using the method explained previously [23], taking into account the ion beam divergence induced by the energy degraders. We have limited our study to the zone situated between 500 and 700 nm, in order to avoid surface effects and the injected interstitial effect [24,25]. Mean damage doses and gas contents for this so-called “analysed zone” between 500 and 700 nm are given in Table 2. Helium and hydrogen to dpa ratios were 17 appmHe/dpa for the dual-beam irradiation and 16 appm He/dpa and 74 appm H/dpa for the triple-beam irradiation, in order to approach conditions predicted for structural materials in fusion reactors [3,26].

After irradiation, transmission electron microscopy (TEM) specimens were prepared by electro-polishing in three steps using a Tenupol 5:

1. Front-side electro-polish to remove 500 nm using a 5% perchloric acid-95% ethanol electrolyte at  $-40$  °C and 40 V.
2. Application of a lacomit layer on the front-side (irradiated side) of the specimen.
3. Back-side electro-polish to pierce a hole with the aforementioned 10% perchloric acid-20% 2-butoxyethanol-70% ethanol electrolyte, at room temperature and 49 V.

Also, transverse specimens were prepared with a focused ion beam (FEI Helios NanoLab 650) and allowed confirmation of the results obtained from the electro-polished specimens.

**Table 2**  
Conditions for irradiations performed at 400 °C in single-, dual- and triple-beam modes. Averages calculated over depths from 500 to 700 nm depth.

Irradiation mode	Dose	Damage rate	Final gas content
Single-beam	26 dpa	$1.4 \times 10^{-3}$ dpa/s	0
Dual-beam	26 dpa	$1.1 \times 10^{-3}$ dpa/s	430 appm He
Triple-beam	27 dpa	$1.3 \times 10^{-3}$ dpa/s	440 appm He, 2000 appm H

The dislocation microstructure, nano-particles and cavities were analyzed using conventional TEM bright field conditions.

Micrographs for dislocation loop density and size analysis were done using  $\vec{g} = \langle 110 \rangle$  type diffraction vectors, and it was verified that using different zone axes did not modify results significantly. Mean loop diameter values were determined by measuring over a hundred loops for each irradiation condition. For one sample, the mean loop diameter was also determined using the weak-beam dark-field method, and the value found was 1.4 nm. The mean loop diameters reported in this study were measured using the conventional bright-field method, leading to a systematic overestimation compared with measurements done with the weak-beam dark-field method. Dislocation loop Burgers vectors were determined using a simplified  $\vec{g} \cdot \vec{b}$  analysis based on the method used by Yao et al. [27,28]. Indeed, unlike samples irradiated as thin foils, where some dislocation loops with Burgers vectors normal to the free surfaces escape to them [29], we can assume that the Burgers vectors are equiprobable amongst a given family (i.e.  $a_0/2 \langle 111 \rangle$  family or  $a_0 \langle 100 \rangle$  family). The respective proportions of  $a_0/2 \langle 111 \rangle$  and  $a_0 \langle 100 \rangle$  type Burgers vectors in a micrograph taken using a diffraction vector  $\vec{g} = [110]$  can be determined by comparison with a micrograph taken using  $\vec{g} = [\bar{1}10]$ , as demonstrated in Fig. 2. Indeed, loops with  $\vec{b} = \pm a_0 [100]$  and  $\vec{b} = \pm a_0 [010]$  are visible in both micrographs whereas loops with  $\vec{b} = \pm a_0/2 [111]$  and  $\vec{b} = \pm a_0/2 [1\bar{1}1]$  are visible in the first micrograph but not in the second. Using the assumption that Burgers vectors are equiprobable amongst a given family, one can then calculate the total proportions of  $a_0/2 \langle 111 \rangle$  and  $a_0 \langle 100 \rangle$  families from the proportions observed in the first micrograph with  $\vec{g} = [110]$ . The proportion of observed  $a_0 \langle 100 \rangle$  Burgers vectors is multiplied by 3/2 and the proportion of observed  $a_0/2 \langle 111 \rangle$  type Burgers vectors is multiplied by 2. In a similar manner, total dislocation loop densities are calculated from the visible loops in a  $\vec{g} = \langle 110 \rangle$  micrograph.

Cavities were analyzed by doing through focal series. Due to the very small sizes of observed cavities, large errors are expected for diameter measurements and density measurements [30].

Thickness measurements were done by counting the thickness fringes in a two-beam bright-field condition or by the contamination spot separation method [31]. The thickness measurement is the major source of errors for dislocation density determinations, and causes an uncertainty of  $\pm 10\%$ .

### 3. Experimental results

#### 3.1. Eurofer-97 and Eurofer-ODS before irradiation

Although excellent studies of non-irradiated Eurofer-97 [2,20] and Eurofer-ODS [32] have already been presented, some details are given here for clarity.

Eurofer-97 has a tempered martensite structure, as can be seen in Fig. 3(a). The dislocation density in the laths is  $9.0 \times 10^{13} \text{ m}^{-2}$ . Precipitates decorate the lath boundaries, but are seldom found inside laths.

Eurofer-ODS has a duplex microstructure: some grains are ferritic (Fig. 3(b)), whereas others contain tempered martensite (Fig. 3(c)). The dislocation and nano-particle microstructures in the two types of grains are different. In the ferrite grains, the dislocation density is  $1.8 \times 10^{13} \text{ m}^{-2}$ , and a high density ( $1.6 \times 10^{22} \text{ m}^{-3}$ ) of relatively small nano-particles is present (Fig. 4(a)). In the tempered martensite grains (Fig. 4(b)), the dislocation density is  $1.3 \times 10^{14} \text{ m}^{-2}$ , and the particles are bigger and their density is lower, at  $5.2 \times 10^{21} \text{ m}^{-3}$ . Particle distributions for the two types of grains are given in Fig. 5: the distribution in the tempered martensite grains is wider and reaches larger sizes. Mean particle diameters are 4.6 nm in ferrite grains and 10.6 nm in tempered martensite grains.

**Fig. 2.** Burgers vector determination in a tempered martensite grain of Eurofer-ODS irradiated to 26 dpa/430 appm He at 400 °C: (a) Bright-field image,  $\vec{g} = [110]$ , (001) pole; (b) Bright-field image,  $\vec{g} = [-110]$ , (001) pole; (c) Bright-field image,  $\vec{g} = [020]$ , (001) pole. Dislocation loops with  $\vec{b} = \pm a_0 [100]$  and  $\vec{b} = \pm a_0 [010]$  are visible in images (a) and (b), and are indexed  $\langle 100 \rangle$  in image (a). Dislocation loops and lines with  $\vec{b} = \pm a_0/2 [111]$  and  $\vec{b} = \pm a_0/2 [11\bar{1}]$  are visible in image (a) but invisible in image (b), and thus can be distinguished from loops with  $a_0 \langle 100 \rangle$  type Burgers vectors. Such loops are indexed as  $\langle 111 \rangle$  and the dislocation lines as  $\langle 111 \rangle$ -D in image (a). Objects with  $a_0/2 \langle 111 \rangle$  type Burgers vectors must be visible in image (c). This enables verification: objects which are visible in image (a) but invisible in image (b) and (c) are indexed as undetermined (Und). Indexes are always to the left of the corresponding object.

**Fig. 3.** Microstructures prior to irradiation in both materials. (a) Eurofer-97; (b) ferrite grain in Eurofer-ODS; (c) tempered martensite grain in Eurofer-ODS.

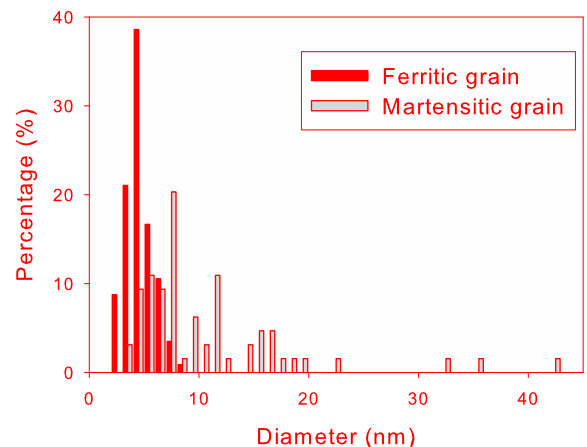

### 3.2. Single-beam irradiation of Eurofer-97 and Eurofer-ODS

After irradiation to 26 dpa at 400 °C, dislocation loops form in both materials (Figs. 6–8). Quantitative data for the dislocation

microstructure formed is indicated in Table 3. In Eurofer-97, the majority of dislocation loops have an  $a_0 \langle 100 \rangle$  type Burgers vector (see Table 4 for Burgers vector analysis) and are situated in  $\{100\}$  type planes (see Fig. 9). A small proportion of the dislocation loops

**Fig. 4.** Precipitate microstructure in Eurofer-ODS. (a) Small precipitates in a ferrite grain; (b) Larger precipitates in a tempered martensite grain.

**Fig. 5.** Precipitate distributions in both grain types in Eurofer-ODS.

**Fig. 6.** Dislocation microstructure in Eurofer-97 irradiated to 26 dpa at 400 °C with 3 MeV Fe<sup>3+</sup> ions (bright-field image,  $\bar{g} = \langle 110 \rangle$ ).

**Fig. 8.** Dislocation microstructure in a ferrite grain of Eurofer-97 irradiated to 26 dpa at 400 °C with 3 MeV Fe<sup>3+</sup> ions (bright-field image,  $\bar{g} = \langle 110 \rangle$ ). White arrows indicate objects counted as dislocation loops.

**Fig. 7.** Dislocation microstructure in a tempered martensite grain of Eurofer-ODS irradiated to 26 dpa at 400 °C with 3 MeV Fe<sup>3+</sup> ions (bright-field image,  $\bar{g} = \langle 110 \rangle$ ).

have  $a_0/2\langle 111 \rangle$  Burgers vectors. Note that all the analyzed dislocation lines have an  $a_0/2\langle 111 \rangle$  Burgers vector.

The dislocation microstructure of the tempered martensite grains of Eurofer-ODS (Fig. 7) is similar to the one observed in Eurofer-97. Dislocation loop densities and sizes are similar, as seen in Table 3. Also, the proportion of loops with  $a_0\langle 100 \rangle$  type Burgers is high in both materials, over 75%.

However, the dislocation microstructure in Eurofer-ODS ferrite grains is quite different (Fig. 8). There are less dislocation loops, but the dislocation network is more developed, so that the dislocation density, which takes into account both dislocation loops and dislocation lines, is quite similar for all types of grains and materials (Table 3). The Burgers vector analysis for ferrite grains shows that most dislocation loops have a  $a_0/2\langle 111 \rangle$  Burgers vector, contrary to the Eurofer-97 and tempered martensite grains of Eurofer-ODS.

For the single-beam irradiation, no cavities are detected in either material. We also note that in both grain types of Eurofer-ODS, no evolution of the oxide particle microstructure is detected.

### 3.3. Multi-beam irradiations of Eurofer-97 and Eurofer-ODS: effects of gas ion implantation

Gas ion implantation has no detectable effect on the densities, size distributions and Burgers vectors of loops, which are similar to the ones determined for the single-beam irradiation in both materials.

However, gas ion implantation has an effect on the cavity microstructure. For both multi-beam irradiations, small cavities are detected in Eurofer-97 and in the tempered martensite grains of Eurofer-ODS. No cavities are detected in the ferrite grains. Measured cavity densities and mean diameters are indicated in Table 5. The cavity microstructure is presented in Figs. 10 and 11 for the dual-beam irradiation and in Figs. 12 and 13 for the triple-beam irradiation. Swelling values calculated from TEM data stay inferior to 0.1% for Eurofer-97 and Eurofer-ODS for both multi-beam irradiations.

Due to the low cavity density and the high irradiation dose, we could not discern whether the cavity formation was heterogeneous or not.

## 4. Discussion

### 4.1. Single-beam irradiation of Eurofer-97 and Eurofer-ODS

Our results concerning Eurofer-97 may be compared to those obtained after neutron irradiations in HFR and BOR-60 [11,12]. Our counting method resembled the one used by Weiss et al. [12], so our results are most easily compared with theirs. After irradiation to 32 dpa at 330 °C, they find a dislocation loop density of  $1.7 \times 10^{22} \text{ m}^{-3}$  and a mean loop size of 4.8 nm. These values are close but inferior to the ones we have observed (see Table 3). This indicates that there is a temperature shift of about 70 °C between neutron and ion irradiation experiments, i.e. to simulate the effects of lower damage rates for neutron irradiations, temperatures higher by 70 °C are necessary for the higher damage rates of ion implantations. Comparison with the work of Klimenkov et al. [11] also supports the fact that the temperature shift is larger than 50 °C, since they report a mean loop diameter size of 35 nm after irradiation to 16.3 dpa at 350 °C. Indeed, although mean loop diameters are not directly comparable, loop diameters of the largest

**Table 3**

Quantitative data for the dislocation microstructure of Eurofer-97 and Eurofer-ODS irradiated to 26 dpa at 400 °C in single-beam mode. The calculated loop density is an estimate including invisible loop populations. Whereas the dislocation densities capture the entire dislocation microstructure, the dislocation loop densities exclude the contribution from dislocation lines.

Material	Eurofer-97	Eurofer-ODS (tempered martensite grains)	Eurofer-ODS (ferrite grains)
Counted dislocation loops	135	195	160
Observed dislocation loop density ( $10^{22} \text{ m}^{-3}$ )	$2.3 \pm 0.2$	$1.2 \pm 0.09$	$0.53 \pm 0.04$
Calculated dislocation loop density ( $10^{22} \text{ m}^{-3}$ )	$3.6 \pm 0.3$	$1.9 \pm 0.1$	$0.96 \pm 0.08$
Mean loop diameter (nm)	$7.9 \pm 0.7$	$7.1 \pm 0.5$	$11 \pm 0.9$
Observed dislocation density ( $10^{14} \text{ m}^{-2}$ )	$6.9 \pm 0.7$	$3.0 \pm 0.1$	$4.0 \pm 0.4$

**Table 4**

Burgers vector analysis of dislocation loops in Eurofer-97 and Eurofer-ODS irradiated to 26 dpa at 400 °C in single-beam mode. Calculated loop proportions are an estimate of the total proportions when including invisible loops and neglecting undetermined objects.

Burgers vector	Eurofer-97	Eurofer-ODS/tempered martensite grain	Eurofer-ODS/ferrite grain
Observed $a_0/2\langle 111 \rangle$ loops	9%	18%	53%
Observed $a_0\langle 100 \rangle$ loops	80%	76%	33%
Undetermined	11%	6%	14%
Number of loops analysed	35	51	21
Calculated $a_0/2\langle 111 \rangle$ loops	13%	24%	68%
Calculated $a_0\langle 100 \rangle$ loops	87%	76%	32%

**Fig. 9.** Dislocation microstructure in Eurofer-97 irradiated to 26 dpa at 400 °C with 3 MeV  $\text{Fe}^{3+}$  ions (bright-field image,  $\vec{g} = \langle 110 \rangle$ ). The majority of the visible loops are edge-on and situated in  $\{100\}$  type planes.

loops rarely exceed 20 nm in our study, so we can conclude that loops are smaller for the ion irradiation.

We show that in Eurofer-97 ion-irradiated to 26 dpa at 400 °C,  $a_0\langle 100 \rangle$  and  $a_0/2\langle 111 \rangle$  type Burgers vectors coexist, and that a majority of the loops have  $a_0\langle 100 \rangle$  type Burgers vector. After neutron irradiation of Eurofer-97 to 32 dpa at 330 °C, both types of Burgers vectors were found, but the majority was  $a_0/2\langle 111 \rangle$  type [12]. This discrepancy could be due to different irradiation temperatures, or to the small number of loops counted. After irradiation in HFR [11], only loops with  $a_0/2\langle 111 \rangle$  type Burgers vectors were found in Eurofer-97 irradiated between 250 °C and 450 °C. The same team has recently indicated that  $a_0\langle 100 \rangle$  loops may also

be present after neutron irradiation at 350 °C [33]. This later finding, which would be more coherent with our result, seems more plausible. Indeed, Horton et al. [34] showed that in pure iron neutron-irradiated to 1 dpa at temperatures between 350 and 450 °C, dislocation loops almost all had  $a_0\langle 100 \rangle$  type Burgers vectors. Gelles [35] observed the microstructure of neutron irradiated Fe–9%Cr and Fe–12%Cr alloys. For irradiation temperatures between 400 and 450 °C, both types of Burgers vectors were present in both materials. Note also that calculations of the anisotropic elastic energy of loops in pure iron showed that loops with  $a_0\langle 100 \rangle$  type Burgers vectors are the most stable at high temperatures [36].

In a 9Cr-ODS steel quite similar to Eurofer-ODS, dislocation loops formed after proton irradiation at 400 °C to about 4 dpa [37]. Loop densities and sizes were somewhat similar to those we observe in the ferrite grains. The loop number density was slightly lower, at  $3.3 \times 10^{21} \text{ m}^{-3}$ , and the reported average size was higher, at 15.4 nm. These differences could be explained by the lower final damage dose and lower damage rate.

For the cavity microstructure, previous neutron-irradiations of Eurofer-97 to 15 and 32 dpa resulted in low densities of small cavities at 330 °C [12]. Our single-beam ion-irradiation experiments to similar doses do not produce any cavities. This may be due to differences in irradiation temperatures and dose rates or due to the fact that for the neutron irradiation, small quantities of helium are produced by transmutation from the few appm of boron, assisting nucleation and stabilization of cavities.

Note that the absence of cavities in a ferritic-martensitic steel ion-irradiated to low dose without helium is not surprising. Previous work on Fe–Cr model alloys [23] has shown that no cavities appear in such materials at doses higher than those attained in this study. No cavities were formed in a Fe–9Cr–1Mo steel ion-

**Table 5**

Quantitative data on densities and sizes of cavities in Eurofer-97 and Eurofer-ODS irradiated to 26 dpa at 400 °C in dual- and triple-beam conditions.

Material	Eurofer-97		Eurofer-ODS (tempered martensite grains)	
Final gas contents	430 appm He	440 appm He/2000 appm H	430 appm He	440 appm He/2000 appm H
Counted cavities	83	165	77	78
Cavity density ( $10^{22} \text{ m}^{-3}$ )	$1.8 \pm 0.2$	$2.3 \pm 0.2$	$1.4 \pm 0.2$	$2.3 \pm 0.3$
Mean cavity diameter (nm)	$1.4 \pm 0.2$	$1.9 \pm 0.1$	$1.8 \pm 0.2$	$2.0 \pm 0.2$

**Fig. 10.** Cavities in Eurofer-97 irradiated to 26 dpa/430 appm He at 400 °C. Bright-field: (a) over-focus: +300 nm; (b) under-focus: -300 nm.

**Fig. 11.** Cavities in a tempered martensite grain of Eurofer-ODS irradiated to 26 dpa/430 appm He at 400 °C. Bright-field: (a) over-focus: +500 nm; (b) under-focus: -500 nm.

**Fig. 12.** Cavities in Eurofer-97 irradiated to 27 dpa/430 appm He/2000 appm H at 400 °C. Bright-field: (a) over-focus: +500 nm; (b) under-focus: -500 nm.

**Fig. 13.** Cavities in a tempered martensite grain of Eurofer-ODS irradiated to 27 dpa/430 appm He/2000 appm H at 400 °C. Bright-field: (a) over-focus: +500 nm; (b) under-focus: -500 nm.

irradiated to 100 dpa at 400 °C and 450 °C [38]. Note that at much higher damage doses, Toloczko et al. [39] observed swelling in EP-450, HT-9 and MA957 ODS to values over 1%. Also, Getto et al. [40] observed cavities in HT9 after irradiation to 140 and 188 dpa at 440 °C with 5 MeV Fe<sup>2+</sup> ions. But similar irradiations to 25 and 50 dpa did not produce any cavities [40], so their results are quite coherent with ours: F/M steels resist swelling when nucleation is not assisted by the presence of helium.

#### 4.2. Multi-beam irradiations of Eurofer-97 and Eurofer-ODS: effects of gas ion implantation

After irradiation to 26 dpa and 430 appm He in dual-beam mode, we observed cavities with a density of  $1.8 \times 10^{22} \text{ m}^{-3}$  and a mean diameter of 1.4 nm in Eurofer-97. After irradiation of the same material to 16.3 dpa and 412 appm He in HFR [6], at conditions that one may consider similar to ours in terms of dose, temperature and helium content, the cavity microstructure was much coarser. Densities and mean cavity sizes were  $0.32 \times 10^{22} \text{ m}^{-3}$  and 10 nm at 350 °C and  $0.24 \times 10^{22} \text{ m}^{-3}$  and 5 nm at 450 °C. As for the dislocation loops, this tends to indicate a temperature shift larger than 50 °C between ion- and neutron-irradiations, although the different helium-to-dpa ratios and the fact that all helium production is nearly finished after 1 dpa in the HFR neutron irradiations may also alter the cavity microstructure.

As for other multi-beam irradiations of F/M steels, they tend to confirm that ion-induced swelling remains low at 400 °C. In a Fe–9Cr–1Mo steel, Farrell and Lee [38] observed the formation of small cavities (~2.0 nm) after irradiation to 106 dpa/1040 appm He/4640 appm D at 400 °C, leading to a swelling of 0.08%. Hiwatashi et al. [41] dual-beam irradiated Fe–9%Cr–2%W and Fe–7%Cr–2%W steels at 15 appm He/dpa to 125 dpa at 400 °C. They observed relatively small cavities and swelling values under 0.1%.

Tanaka et al. [42] irradiated Fe–12%Cr and Fe–9%Cr model alloys in triple-beam (Fe, He and H ions) and dual-beam (Fe and He ions) modes to 50 dpa with fusion relevant conditions. At 510 °C, the comparison of these two types of irradiation demonstrated that hydrogen injection induces additional cavity growth and swelling. In our experiments, the cavity sizes and densities seem to be slightly higher when hydrogen is injected in both materials. However, due to large error bars at such small cavity sizes, it is difficult to conclude that hydrogen has effectively played a role. This discrepancy with work by Tanaka et al. may be due to the lower temperature in our study. It could also be related to the lower dose in our study: cavity growth, for which hydrogen may play a role, is not yet active. Note that Farrell and Lee concluded for their ion-irradiations of a Fe–9Cr–1Mo steel [38] that the co-injection of hydrogen had a low impact on the overall cavity microstructure. More dual- and triple-beam irradiations at other temperatures and doses are necessary to comprehend the effect of hydrogen.

For Eurofer-ODS, the different behaviours between the tempered martensite grains and ferrite grains under dual- and triple-beam experiments can be explained as follows. In the tempered martensite grains, implanted helium atoms will instantly be captured by a vacancy, due to the very low interstitial helium migration energy [43] and the very high quantity of vacancies created in cascades. According to our calculations done with SRIM [21] and presented in Section 2, more than fifty thousand vacancies are created for each helium atom implanted during the irradiation. The combination of a vacancy and a helium atom form a substitutional helium atom, which probably migrates via the vacancy mechanism with an activation energy close or higher than the one calculated in iron (1.1 eV) by *ab initio* methods [43]. Thus this

substitutional helium atom may migrate over small distances at 400 °C, but will also lead to the formation of small helium-vacancy clusters, nuclei of cavities. However, in the ferrite grains, it may be postulated that the higher density of nano-particles will tend to capture all helium atoms at their interfaces, reducing the possibility for nucleation of cavities in these zones. As a result, the high density of smaller ODS nano-particles in the ferrite grains inhibits cavity formation.

The question of knowing whether helium actually accumulates on ODS particles has been addressed by Badjeck et al. [44] who studied the distribution of Ti and He by EELS using an ultra-STEM in an ODS steel irradiated in dual-beam mode (Fe and He ions). In their study some of the helium was detected on ODS particles. Qian et al. [45] have also studied the distribution of helium in an ODS steel by APT after a single-beam He<sup>+</sup> irradiation at 400 °C. They found that only about 5% of helium was correlated with nano-particles. However the authors indicate that for irradiations in nuclear reactors (or dual-beam irradiations), the situation may be different due to a very different He/dpa ratio. Experimental studies like these could help us confirm the role of the high-density of nano-particles in the ferrite grains in our case.

## 5. Conclusion and acknowledgments

We have performed single-, dual- and triple-beam ion irradiations of Eurofer-97 and Eurofer-ODS steels to 26 dpa at 400 °C. Microstructural damage was characterized by TEM. The following conclusions may be drawn for the two steels irradiated to 26 dpa at 400 °C:

- Under single-beam Fe<sup>3+</sup> ion irradiation, dislocation loops form in both Eurofer-97 and Eurofer-ODS. No cavities are detected.
- Simultaneous gas ion implantation does not affect the dislocation microstructure formed under irradiation. However, it induces the formation of cavities in Eurofer-97 and in the tempered martensite grains of Eurofer-ODS.
- Low cavity diameters in dual- and triple-beam modes indicate low swelling (<0.1%) for both materials.
- A high-density of ODS nano-particles such as in the ferrite grains of Eurofer-ODS inhibits cavity formation.

Experiments done at JANNuS (Joint Accelerators for Nanoscience and Nuclear Simulation), Saclay, France and supported by EFDA (European Fusion Development Agreement) and the French network EMIR.
