ABSTRACT

A polycrystalline dislocation-based cyclic viscoplastic model is proposed to predict the cyclic behaviour of 316LN austenitic stainless steels at room temperature (RT). The evolution laws of the densities of different populations of dislocations are described, by taking into account physical mechanisms of crystal viscoplasticity. The comparison between the predictions and corresponding experimental results shows that the cyclic behaviour of 316LN stainless steel is reasonably well described. Notably, a reduced number of adjusted crystal viscoplasticity parameters is used and only tensile and relaxation curves are used in the adjustment procedure.

Dislocation density, polycrystal, elasto-viscoplasticity, cyclic behaviour, ratcheting, 316LN stainless steel

INTRODUCTION

Many experimental studies have been carried out in order to understand the cyclic behaviour of the polycrystalline 316LN austenitic stainless steel, largely used in nuclear power plants. The first studies have mainly characterized the macroscopic behaviour under different loading conditions, allowing the development and application of different phenomenological models, reviewed in [1,2].

From observations made by many authors, different micromechanical models have been proposed for the prediction of the 316LN stainless steel [3–5]. Despite the fact that these models better describe the deformation process by taking into account some of the physical mechanisms of deformation, they usually require the adjustment of numerous parameters, involving experimental cyclic test in the adjustment process.

The aim of this work is to apply a micro-mechanical modelling to predict the cyclic behaviour (fatigue and ratcheting) of 316LN stainless steel at RT with a number of adjustable parameters as low as possible. At the crystal scale, the constitutive laws describe the evolution of the densities of the different populations of dislocations. A self-consistent localization rule is used to compute the homogenized stress-strain curves. This self-consistent mean-field homogenization rule has been validated with respect to numerous full-field finite-elements results in the considered range of plastic strain amplitude [6]. The response of the proposed model is compared to experimental data, taken from Gaudin [3] and Gentet [7].

DISLOCATION-BASED CONSTITUTIVE MODEL

The dominant mechanism of plastic deformation is mainly dislocation glide along active slip systems. For a FCC structure, the dense $\{111\}$ planes and the dense $\langle 110 \rangle$ directions allow the definition of the twelve easy slip systems. The resolved shear stress, τ_i , result from the projection of the local stress tensor, $\underline{\sigma}$, on slip system i .

$$\tau_i = \underline{\sigma} : (\underline{m}^i \otimes \underline{n}^i) \quad \text{Equation 1}$$

In Equation 1, \underline{m}^i is the unit slip direction vector and \underline{n}^i the unit normal vector to the slip plane. Dislocation glide occurs only as the resolved shear stress (τ_i) on the slip system, i , reaches a critical stress value ($\tau_{c,i}$). The critical resolved shear stress is computed using all the dislocation densities in all slip systems (j), including (i) itself [8,9]:

$$\tau_{c,i} = \mu b \sqrt{\sum_{j=1}^{12} h_{ij} \rho^j} \quad \text{Equation 2}$$

μ is the elastic shear modulus, b is the length of the Burgers vector and h_{ij} is a 12x12 interaction matrix, that represents the strength of the interaction between the slip systems (i) and (j). According to the theory of thermally activated processes [10], non-zero viscoplastic slip rate on slip system (i) requires a positive effective stress, τ_i^* :

$$\tau_i^* = |\tau_i| - \tau_{c,i} \quad \text{Equation 3}$$

The viscoplastic slip rate ($\dot{\gamma}_i^p$) is expressed in Equation 4 and Equation 5, for edge and screw dislocation segments, defined by the subscript letter e and s , respectively. These expressions reflect the correlation between the plastic slip rate on a slip system (i), and the effective stress, τ_i^* [11]. In these equations T denotes the temperature, V the activation volume, Q the activation energy, κ_b the Boltzmann constant and ν_D the Debye frequency.

$$\dot{\gamma}_{i,e}^p = 2\nu_D b^2 \rho_e^i \cdot \exp\left(-\frac{Q}{\kappa_b T}\right) \cdot \sinh\left(\frac{V\tau_i^*}{\kappa_b T}\right) \quad \text{Equation 4}$$

$$\dot{\gamma}_{i,s}^p = 2\nu_D b^2 \rho_s^i \cdot \exp\left(-\frac{Q}{\kappa_b T}\right) \cdot \sinh\left(\frac{V\tau_i^*}{\kappa_b T}\right) \quad \text{Equation 5}$$

For each slip system, three families of dislocations are considered: edge dislocations, ρ_e^i , screw dislocations, ρ_s^i , and dipole dislocations, ρ_d^i . The evolution laws of the densities of each family are associated with the mechanisms observed experimentally [9,11–13].

Equation 6 and Equation 7 provide the expressions of the edge and screw dislocation density rates, respectively. The evolution of both is defined by a first production term, describing the multiplication mechanisms, and a second one, representing the annihilation mechanisms. In addition, a third term is introduced in the edge dislocation density evolution law, representing the formation of dipoles. Equation 8 provides the expression of the dipole density rate, composed by one term of production and one of annihilation.

$$\dot{\rho}_e^i = \frac{2}{bL} \cdot |\dot{\gamma}_s^i| \cdot \text{sign}\left(\frac{\dot{\gamma}_s^i}{\dot{\gamma}_s^i}\right) - \frac{2y_e}{b} \cdot \rho_e^i \cdot |\dot{\gamma}_e^i| - 2\rho_e^i \cdot \frac{h_{max} - y_e}{b} \cdot |\dot{\gamma}_e^i| \quad \text{Equation 6}$$

$$\dot{\rho}_s^i = \frac{2}{bL} \cdot |\dot{\gamma}_e^i| \cdot \text{sign}\left(\frac{\dot{\gamma}_e^i}{\dot{\gamma}_e^i}\right) - \frac{2y_s}{b} \cdot \rho_s^i \cdot |\dot{\gamma}_s^i| \quad \text{Equation 7}$$

$$\dot{\rho}_d^i = 2\rho_e^i \cdot \frac{h_{max} - y_e}{b} \cdot |\dot{\gamma}_e^i| - \frac{2y_e}{b} \cdot \rho_d^i \cdot |\dot{\gamma}_e^i| \quad \text{Equation 8}$$

The maximum distances of annihilation of edge and screw dislocations are denoted as y_e and y_s , respectively. The maximum dipole height, h_{max} , and the mean-free path of a mobile dislocation, L , are expressed by:

$$L = \min\left(\phi, \frac{\kappa}{\sqrt{(\rho_e + \rho_s + \rho_d)}}\right) \text{ and } h_{max}^i = \frac{\mu b}{8\pi(1-\nu)\tau_{c,i}} \quad \text{Equation 9}$$

where ϕ is the mean grain size, κ is a production parameter (free-mean path of mobile dislocations) defined for different crystal orientations, as explained in the following, and ν is the Poisson ratio.

Since the crystal orientation affects the deformation behaviour [14], two families of crystals are considered in this work. The first family assembles the crystals oriented for single slip, located in the central part of the standard triangle and in the [110] corner. The second family gathers the crystals oriented for extended multiple slip, located near the [100] and [111] corners of the standard triangle. The partitioning between the two families is carried out by using a critical value (R_{crit}) of the ratio between the cross-slip resolved shear stress and the primary one (Figure 1). That is a straightaway for reproducing more simply the density evolution laws proposed by Kubin et al. [9]. By taken experimental tensile curves of copper single crystals [15,16] and TEM observations of FCC metals/alloys [3,17,18], the critical ratio value has been determined as $R_{crit}=0.61$.

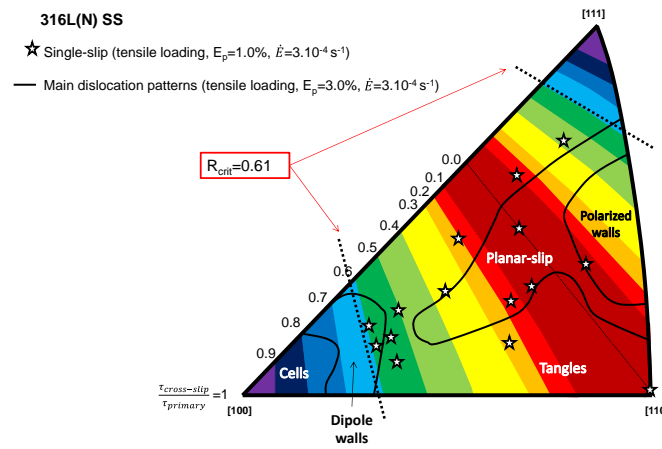

Figure 1. Iso-values of the ratio between $|\tau_{cross\ slip}/\tau_{primary}|$ plotted in the standard crystallographic triangle. The indicated dislocation patterns, observed by TEM for a 316LN stainless steel alloy, are taken from [3].

The criterion $|\tau_{cross\ slip}/\tau_{primary}| < R_{crit}$ is used to define the free-mean parameter for each grain orientation (κ_{single} and κ_{multi}) and also to delay the activation of multiple slip systems in the crystals oriented for single slip. For this, a higher value of latent hardening coefficient ($h_{ij} = h_{latent}^{single}$) (Equation 2) is considered. For the crystals oriented for multiple slip, the interaction coefficients are the ones computed by dislocation dynamics [9].

Finally, the self-consistent rule proposed by Kröner [15] is applied in order to link the local behaviour (grain scale) with the overall material behaviour (polycrystal scale). In previous work [6], its predictions were compared with the FE ones. A fair agreement was found for different stress-sensitivity and under different loading conditions. This corresponding localization rule can be written by:

$$\underline{\dot{\sigma}} = \underline{\dot{\Sigma}} + 2\mu(1 - \beta) (\underline{\dot{E}}^{in} - \underline{\dot{\epsilon}}^{in}) \quad \text{with} \quad \beta = \frac{2(4-5\nu)}{15(1-\nu)} \quad \text{Equation 10}$$

where $\underline{\dot{\sigma}}$ and $\underline{\dot{\epsilon}}^{in}$ are the average grain stress and inelastic strain rates tensors and $\underline{\dot{\Sigma}}$ and $\underline{\dot{E}}^{in}$ are their average at the polycrystal scale.

IDENTIFICATION OF THE PARAMETER AND PHYSICAL CONSTANTS

A random crystal distribution in an aggregate of grains is considered, allowing an overall isotropic behaviour. The calculations are carried out using the SiDoLo software [19]. The polycrystalline aggregate is composed by 100 grains. Table 1 summarizes the physical

constants and material parameters, determined experimentally or by dislocation dynamics (DD) simulations. The reference of each parameter measurement is also indicated.

The material parameters related to the thermally activated mechanisms (activation volume, V , and activation energy, Q) are the only parameters identified from experimental results, by inverse identification. The adjustment is made by using stress relaxation data at RT and tensile tests at different temperatures (RT, 373K and 473K) but at the same strain rate. The adjustment of these are $V=100b^3$ and $Q=1.48$ eV. The calculated curves using these viscoplastic parameters are compared with experimental data in Figure 2.

Parameter		Value	Ref.	
κ_b	Boltzmann constant	$1.38 \cdot 10^{-23} \text{ J.K}^{-1}$	[10]	Cst.
ν_D	Debye frequency	10^{13} s^{-1}	[10]	Cst.
E	Young's modulus	195000 MPa	[3]	Exp.
ν	Poisson's ratio	0.3	[3]	Exp.
b	Burgers vector magnitude (FCC material)	$2.56 \cdot 10^{-10} \text{ m}$	[10]	Exp.
γ_e	Annihilation distance of edge dislocations	$1.2 \cdot 10^{-9} \text{ m}$	[3]	Exp.
γ_s	Annihilation distance of screw dislocations	$15 \cdot 10^{-9} \text{ m}$	[3]	Exp.
κ_{single}	Free-mean path parameter for single slip crystals	300	[20]	Exp.
κ_{multi}	Free-mean path parameter for multiple slip crystals	30	[20]	Exp.
R_{crit}	Critical ratio	0.61	[20]	Exp.
ϕ	Grain size	$50 \cdot 10^{-6} \text{ m}$	[3]	Exp.

PREDICTIONS AND DISCUSSIONS

Uniaxial strain-controlled cyclic loading at different temperatures are first simulated using $E \pm 0.575\%$ and $\dot{E} = 3.10^{-4} \text{ s}^{-1}$ (Figure 3). The predicted curves are in fair agreement with

the experimental data for the first 50 cycles. At this point, slight softening is observed experimentally, while cyclic hardening is still predicted by the model. Since the model is not able to reproduce cyclic softening, the stress amplitude is slightly overestimated after 100 cycles. Some additional physical mechanisms should be considered for predicting that slight softening.

The shape of the first loop is also well predicted. But a difference between the experimental and the simulated reverse yield point is observed. This difference is assigned to the calculation of the kinematic stress. The kinematic stress can be defined by the addition of two components: an intragranular kinematic stress, characterizing the heterogeneous dislocations distribution inside the grains, and an intergranular kinematic stress, representing the incompatibilities between grains [21]. In this work, the mechanisms of multiplication, annihilation and interaction between dislocations are described, but not the evolution of dislocations patterns during the cyclic loading. An improvement of the model is envisioned to introduce an intragranular kinematic stress law, based on the prediction of dislocations patterns.

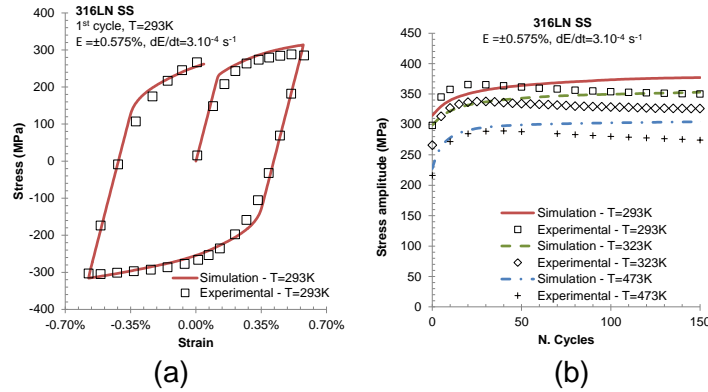

Figure 3. 1st loop (a) and stress amplitude evolution (b) for the 316LN stainless steel tested under uniaxial plastic strain-controlled cyclic loading, with $E = \pm 0.575\%$ and $\dot{E} = 3.10^{-4} s^{-1}$. Experimental data are taken from [7].

Under asymmetrical stress cycling, one observes a cyclic accumulation of strain, namely ratcheting. The ratcheting strain is defined in this work as the mean plastic strain at each cycle. In Figure 4, the predicted ratcheting strain is compared to experimental data [3].

Figure 4. Ratcheting strain for the 316LN stainless steel. (a) $\Sigma_m = 50$ MPa and different stress amplitudes (Σ_{amp}); (b) $\Sigma_{max} = 350$ MPa and $\Sigma_{max} = 450$ MPa, and different mean stresses. Experimental data are taken from [3].

Firstly, the same mean stress ($\Sigma_m = 50$ MPa) is applied, for different stress amplitudes (Σ_{amp}) (Figure 4a). The behaviour is fair well predicted for the lower stress amplitude, but the ratcheting strain is overestimated for the highest value of Σ_{amp} . Then, the ratcheting

behaviour is assessed for maximum stresses (Σ_{max}) of 350 MPa and 450 MPa, with different mean stresses (Figure 4b). The ratcheting behaviour is better described for a low maximum stress ($\Sigma_{max}=350$ MPa). For both mean stresses, the ratcheting strain is slightly underestimated, but the ratcheting evolution is fairly well described. In the case of the highest maximum stress ($\Sigma_{max}=450$ MPa), the model tends to overestimate the ratcheting strain after a few cycles. The ratcheting strain increases more quickly than observed experimentally during the first cycles, resulting in a different shape of the ratcheting strain evolution curve.

Although the behaviour is fairly well predicted, the model could result in a better description of the ratcheting strain by improving the reverse yield point simulation.

Conclusions

A dislocation-based viscoplasticity model to predict the cyclic behaviour of 316LN stainless steels at room temperature was presented. Experimental tensile and relaxation curves of a 316LN stainless steel were considered for the adjustment of the two viscoplasticity parameters. The proposed model provided rather fair predictions of the fatigue and ratcheting behaviours, comparing with the experimental data. Notwithstanding, some improvements should be made in order to better predict the behaviour of the material (i.e. softening behaviour, intragranular kinematic stress description). For future work, the model will be upgraded to take into account the physical mechanisms of cyclic deformation at higher temperatures ($T>723$ K), wherein the dynamical strain ageing (DSA) plays an important role in the glide of dislocations and the cyclic behaviour.
