Environmental mobility of $^{110m}$Ag: lessons learnt from Fukushima accident (Japan) and potential use for tracking the dispersion of contamination within coastal catchments

Abstract

Silver-110 metastable ($^{110m}$Ag) has been far less investigated than other anthropogenic radionuclides, although it has the potential to accumulate in plants and animal tissues. It is continuously produced by nuclear power plants in normal conditions, but emitted in much larger quantities in accidental conditions facilitating its detection, which allows the investigation of its behaviour in the environment. We analysed $^{110m}$Ag in soil and river drape sediment (i.e., mud drapes deposited on channel-bed sand) collected within coastal catchments contaminated in Fukushima Prefecture (Japan) after the Fukushima Dai-ichi Nuclear Power Plant accident that occurred on 11 March 2011. Several field experiments were conducted to document radiosilver behaviour in the terrestrial environment, with a systematic comparison to the more documented radiocesium behaviour. Results show a similar and low mobility for both elements in soils and a strong affinity with the clay fraction. Measurements conducted on sediment sequences accumulated in reservoirs tend to confirm a comparable migration and deposition of those radionuclides even after their redistribution due to erosion and deposition processes. Therefore, as the $^{110m}$Ag:$^{137}$Cs initial activity ratio varied in soils across the area, we justified the relevance of using this tool to track the dispersion of contaminated sediment from the main inland radioactive pollution plume generated by FDNPP accident.
1. Introduction

Silver-110 metastable ($^{110m}\text{Ag}$) is a radioisotope with a rather short half-life of 249 days produced in nuclear power plants (NPP) as an activation product of $^{109}\text{Ag}$. In NPP, natural silver (which contains 48% of $^{109}\text{Ag}$) is found in control rods or in the alloy used to seal the head of the reactor (Calmon and Garnier-Laplace 2002; Chelet 2006; IAEA 1998). In addition, $^{109}\text{Ag}$ may also be a fission product from uranium and plutonium (Chelet, 2006). $^{110m}\text{Ag}$ can be measured by spectrometry gamma (with the main peak at 658 keV, and secondary peaks at 885 and 937 keV).

Le Petit et al. (2012) described the $^{110m}\text{Ag}$ as a volatile fuel particle displaying some common characteristics with semi-volatile substances, due to its well-known strong retention within the reactor core structures. Even though $^{110m}\text{Ag}$ is produced by NPP in normal operational conditions, its release into the environment remains limited (Ciffroy et al., 2005; Eyrolle et al., 2012) (Table 1), and research on this radionuclide has mainly gained interest after Chernobyl and Fukushima Dai-ichi accidents when it was emitted in much larger quantities, which facilitated its measurement. A search of the Web of Knowledge citation index (July 2013) shows that the number of publications about $^{110m}\text{Ag}$ increased significantly after Chernobyl accident (Fig. 1). A similar increase in attention has already been observed shortly after Fukushima accident.

Few information are available on the environmental mobility of $^{110m}\text{Ag}$, and most of the studies regarding this radioisotope were conducted in laboratory (Calmon and Garnier-Laplace 2002) because the conditions necessary to conduct field experiments were rarely met, as samples should be collected within the months following a release. They should alternatively be recovered in large quantities and analysed with high sensitivity detectors.
during relatively long counting times. Still, it remains important to better understand its behaviour in the environment, as it has been demonstrated that silver is one of the most toxic metals (Bryan, 1971; Ratte, 1999) and that $^{110m}$Ag may be transferred from the soils to the plants (Handl et al., 2000; Shang and Leung, 2003), and accumulated in animal tissues (Adam et al., 2001; Beresford et al., 1998; Bryan and Langston, 1992; Khangarot and Ray, 1987; Martin and Holdich, 1986; Oughton, 1989). It can also contaminate natural silver (isotopic contamination) used for photographic industry and jewellery manufacturing (Vuković, 2002).

Besides this interest to better understand the radioecology of $^{110m}$Ag, it has been shown that this radioisotope was emitted by the Fukushima Dai-ichi Nuclear Power Plant (FDNPP) accident and subsequently detected in the environment (Fukuda et al., 2013; MEXT, 2011; Tazoe et al., 2012; Watanabe et al., 2012). It is estimated that 20% of the radionuclides emitted were deposited on the soils of Fukushima Prefecture as a result of wet and dry atmospheric fallout, creating a contamination plume extending up to 70 km to the northwest of the FDNPP site (Kinoshita et al., 2011; Yasunari et al., 2011). It was estimated that between 7 and 36 PBq of $^{137}$Cs ($T_{1/2} = 30.17\text{y}$) were released (Chino et al., 2011; Stohl et al., 2012; Winiarek et al., 2012), and $^{110m}$Ag release rate represented about 11% of the $^{137}$Cs rate (Petit et al., 2012).

Depending on the behaviour of the radionuclides and their affinity with the fine mineral particles and the associated organic matter fraction, they may subsequently be redistributed across hillslopes as a consequence of runoff and soil erosion processes and be delivered to downstream rivers that may finally supply them to the ocean (Tanaka et al., 2012; Tateda et al., 2013; Ueda et al., 2013). Even though the bulk of initial marine contamination originated
from atmospheric deposition, erosion processes may have partly supplied the $^{110m}$Ag that
was detected in zooplankton in the Pacific Ocean shortly after the accident (Buesseler et al.,
2012).

In order to document this transfer, Chartin et al. (2013) showed that the spatial patterns of
$^{110m}$Ag:$^{137}$Cs activity ratio in soils varied across space within the Fukushima contamination
plume. They subsequently used this ratio to track the dispersion of contaminated sediment
along a coastal river draining a catchment located within the main radioactive plume.

However, to date, most studies conducted in Fukushima post-accidental conditions focused
on $^{134}$Cs and $^{137}$Cs behaviour (Inoue et al. 2013; Koarashi et al. 2012; Kato et al. 2012a,
2012b; Matsunaga et al. 2013). Investigations reporting the presence of $^{110m}$Ag in soil did not
detail its distribution with depth nor its behaviour (Fukuda et al., 2013; Tazoe et al., 2012;
Watanabe et al., 2012). In this context, there is a lack of data collected in this specific post-
accidental context to document the relative behaviour of $^{110m}$Ag and $^{137}$Cs in soils and
sediment in order to check the relevance of using this ratio to track the dispersion of
contaminated material along rivers. Even though both radionuclides are particle-reactive,
the $^{110m}$Ag:$^{137}$Cs activity ratio in mobilized sediment might not simply reflect the catchment
soil average of this ratio.

In this context, this paper aims to compile original experimental data acquired in Fukushima
Prefecture during the months that followed the accident to document $^{110m}$Ag behaviour in
soils and sediment. This paper will particularly address four issues:

1. the affinity of $^{110m}$Ag with different grain size fractions, to check whether there is a
different behaviour of $^{110m}$Ag and $^{137}$Cs depending on the particle size;

2. the migration of $^{110m}$Ag in the soil, to investigate its potential movement with depth;
(3) the evolution of $^{110m}$Ag activities within sediment sequences accumulated in reservoirs, to document whether characteristics of contaminated sediments delivered to the reservoir by successive flood events change with time;

(4) the evolution of $^{110m}$Ag activities within sediment drape deposits, that consist of mud drapes deposited on channel-bed sand (Olley et al., 2013), collected at the same locations along the rivers after a succession of typhoon and snowmelt events to investigate the impact of those events on $^{110m}$Ag redistribution in catchments.

We will systematically compare the radiosilver behaviour to the one of the well documented radiocaesium, and to the literature data. The implications of those results will finally be discussed to decide whether the use of the $^{110m}$Ag:$^{137}$Cs activity ratio is relevant to track the dispersion of contaminated sediment from the main radioactive pollution plume generated by FDNPP accident.

2. Materials and methods

2.1. Study area

The study was conducted in Fukushima Prefecture, located in Northeastern Japan. We focused on several coastal catchments (i.e. Mano, Nitta, Ota and Odaka catchments) (1000 km²) draining the main part of the radioactive plume extending to the northwest of FDNPP (Fig. 2). Those catchments extend from the coastal mountain range (at approximately 30-km distance of the coast) to the Pacific Ocean and their elevation ranges from 0 to 900 m.

Plateaus on the west consist of Cretaceous granite and granodiorite, evolving into a complex patchwork of volcanic (both intrusive and extrusive), metamorphic (gneiss and schist) and plutonic (granite mainly) rocks. In the middle part of the catchments, marine and continental
sedimentary rocks of various ages separated by fault systems are found. In contrast, eastern coastal plains are mainly composed of Tertiary and Quaternary marine and continental sedimentary rocks.

Woodland is the main land use in this area (covering 68–78% of the total surface), followed by cropland (10–13%). The region is exposed to typhoons and spring snowmelt events leading to severe soil erosion and subsequent export of sediment in rivers (Chartin et al., 2013; Evrard et al., 2013). We therefore conducted three sampling campaigns after each of those major hydro-sedimentary events (i.e., Nov. 2011, April 2012, and Nov. 2012).

2.2. Sample collection, preparation and description of experiments.

After the accident, the Ministry of Education, Culture, Sports, Science and Technology in Japan (MEXT) supervised the sampling of soils at 2200 sites located within a radius of approximately 100 km around FDNPP in June and July 2011, and the analysis of their activities in several radionuclides contained in their 5-cm upper layer ($^{110m}$Ag activities were only provided for a selection of 345 sites; MEXT 2011).

Based on this dataset, a map of $^{110m}$Ag:$^{137}$Cs activity ratio values in soils was drawn (Chartin et al., 2013). Unlike $^{134}$Cs:$^{137}$Cs activity ratio, it revealed the presence of different contamination patterns across the area (Fig. 3), with lower values across mountains and higher values in the coastal lowlands.

The relatively low abundance of $^{110m}$Ag in soils of the study area in Fukushima (activities ranging between 2 – 2400 Bq kg$^{-1}$) compared to those in $^{134}$Cs and $^{137}$Cs (500 – 1,245,000 Bq kg$^{-1}$) required relatively long counting times and the use of low-background high-resolution detectors to allow its detection. This probably explains why this radioisotope has not been
measured more widely during the months that followed the accident. We therefore decided
to restrict this study to the main contamination plume (Table 2) in order to minimize
uncertainties associated with $^{110m}\text{Ag}$ measurements.

A. Behaviour of $^{110m}\text{Ag}$ in soils

Experiment 1 – Affinity with different grain size fractions

Four soil samples (~300g/sample – Soil 1 to Soil 4 - Fig. 3) were collected using non-metallic
trowels in different parts of the contamination plume where $^{110m}\text{Ag}$:$^{137}\text{Cs}$ activity ratio varies
from 0.002 to 0.008. After drying at 40°C, samples were dry-sieved to 1mm, 500µm, 250µm
and 63µm using an automatic device, in order to measure the respective activities present in
the different grain size fractions.

Experiment 2 – Migration in soil

To investigate the potential migration of radionuclides with depth in soil, gamma
measurements were conducted on each 2-mm increment of the uppermost 2-cm of a soil
profile sampled near Kawamata city (Profile - Fig. 3). Soil layers were collected using a
scraper plate composed by a metal frame and a metal plate (Loughran et al., 2002; Kato et
al., 2012b). To avoid contamination by top layers, a spray glue was used to fix the sample.

$^{137}\text{Cs}$ concentration in undisturbed Japanese soils is expected to show an exponential decline
with depth (Kato et al., 2012b; Koarashi et al., 2012; Matsunaga et al., 2013). Cumulative
inventory can be expressed as described in Eq. (1):

\[ I(x) = I_t \left(1 - \exp^{-x/h_0}\right) \]  \hspace{1cm} (1)
Where \( I(x) \) is the radiocesium inventory (Bq.m\(^{-2}\)) at the \( x \) (kg.m\(^{-2}\)) depth, \( I_t \) is the total radiocesium inventory and \( h_0 \) is the relaxation mass depth (kg.m\(^2\)), an index characterising the radiocesium penetration in the soil. In order to use this formula, we calculated the \(^{137}\)Cs inventory using \(^{137}\)Cs activities (Bq.kg\(^{-1}\)) (Lee et al., 2013) at the successive (x) depths (Eq. 2):

\[
I(x) = \rho(x) \times h(x) \times A(x) \quad (2)
\]

Where \( \rho \) is the dry bulk density (g.m\(^{-3}\)), \( h \) is the thickness (cm) of the layer and \( A \) the activity (Bq.kg\(^{-1}\)) of this layer.

**B. Behaviour of \(^{110m}\)Ag in rivers**

*Experiment 3 – Activities in sediment sequences accumulated in reservoirs*

During the November 2012 fieldwork campaign, we had the opportunity to collect samples of the different layers representative of the deep sediment sequence that accumulated behind Tetsuzen dam on Ota River (1.6 m) and behind Takanokura dam on Mizunashi River (Nitta catchment) (0.5 m) in order to investigate \(^{110m}\)Ag behaviour in respectively 9 and 7 different layers (Dam Sed 1 and Dam Sed 2 - Fig. 3). We removed the exposed sediment lateral surface to avoid artificial sample contamination during fieldwork.

Particle size of the samples was measured using a SALD-3100 Laser (Shimadzu Co., Ltd., Kyoto, Japan) following standard procedures. The particles were classified into 42 size ranges between 0.05 and 450\( \mu \)m. The surface specific area was estimated using the density of quartz (2.65g cm\(^{-3}\)) and assuming that particles were spherical (Santamarina and Klein, 2002). Grain size distribution was corrected using sieving data for classes >450\( \mu \)m, and final classes were reclassified according to the grain-size ranges proposed by AFNOR X 316107 (i.e., clay <2\( \mu \)m, 2 \( \mu \)m < silt < 50\( \mu \)m, 50\( \mu \)m < sand < 2mm).
Experiment 4 – Impact of typhoon and snowmelt on activities in river drape sediment

A last experiment was conducted in upper parts of the Nitta River catchment (with elevation > 400m), where the $^{110m}\text{Ag}:{^{137}}\text{Cs}$ activity ratio in soils is low but overall radioactive contamination is high. This area was impacted by summer typhoons and spring snowmelt events that generated soil erosion on hillslopes and led to an increase in river discharge (Fukuyama et al., 2005; lida et al., 2012; Ueda et al., 2013). Sediment drape deposits (SDD) were selected as an alternative to suspended sediment in order to increase the spatial coverage of the survey within the catchments, and to avoid the logistical problems associated with the collection of suspended sediment in rivers. Olley et al. (2013) demonstrated that sediment source apportionment conducted on SDD and suspended matters showed similar results. To prepare a representative sample, five to ten subsamples that are likely to have deposited after the last major flood were collected at several locations selected randomly down to the underlying coarser cobble or gravel layer across a 10m$^2$ surface. Sediment drape deposits are likely to integrate deposits of the last hydro-sedimentary events of low to intermediate magnitude (Evrard et al., 2011) even though the occurrence of large floods probably leads to a complete flush of the system justifying the relevance of conducting field surveys to collect sediment drape deposits as frequently as possible.

Activities were measured in 4 representative SDD samples collected at the same location during the four successive fieldwork campaigns (SDD 1 to SDD 4 - Fig. 3). Grain size measurements were conducted by following the same protocol as described for Experiment 3.

2.3 Gamma spectrometry measurements
Before measurement, samples were dried at 40°C (105°C for soil), ground to a fine powder and then packed into 15mL polyethylene specimen cups. Radionuclide activities ($^{134}$Cs, $^{137}$Cs, $^{110m}$Ag) in all samples were determined by gamma spectrometry using very low-background coaxial N- and P-types HPGe detectors (Canberra / Ortec). Counting times of soil and sediment samples varied between $8 \times 10^4$ and $200 \times 10^4$ s to allow the detection of $^{110m}$Ag, which was present in much lower activities in the samples ($2$–$2400$ Bq.kg$^{-1}$) than $^{134}$Cs and $^{137}$Cs ($500$–$1,245,000$ Bq.kg$^{-1}$).

The $^{137}$Cs activities were measured at the 661 keV emission peak. The $^{134}$Cs ($T_{1/2} = 2\mu y$) activities were calculated as the mean of activities derived from measurements conducted at 604 keV and 795 keV ($^{228}$Ac activities being negligible compared to $^{134}$Cs activities) as both peaks are associated with the largest gamma emission intensities of this radionuclide.

The presence of $^{110m}$Ag was confirmed by the detection of an emission peak at 885 keV (as the peak associated with the largest emission intensity at 658 keV was masked by the 661-keV peak of $^{137}$Cs). Minimum detectable activities in $^{110m}$Ag for 24h counting times reached $2 \times 10^2$ Bq.kg$^{-1}$. Detection of $^{110m}$Ag was considered relevant when the 885 keV peak was present.

Because of their low level, activities in $^{110m}$Ag were associated with larger uncertainties than activities in $^{137}$Cs. Counting efficiencies and quality assurance were conducted using internal and certified International Atomic Energy Agency (IAEA) reference materials prepared in the same specimen cups as the samples. Uncertainties on results were estimated by combining counting statistics and calibration uncertainties. Summing and self-absorption effects were taken into account by analysing standards with similar densities and characteristics as the collected samples. All radionuclide activities were decay corrected to the date of 14 March 2011 corresponding to the date of the first radionuclide deposits on soils. Most of them
were estimated to have deposited on 15 March in Fukushima Prefecture (Kinoshita et al., 2011; Shozugawa et al., 2012).

3. Results and discussion

A. Behaviour of $^{110m}$Ag in soils

Experiment 1 – Affinity with different grain size fractions (Soil 1 to Soil 4)

During this experiment, $^{110m}$Ag activities could only be detected in all fractions for 2 of the 4 analysed samples (Soil 1 and Soil 2 – Fig. 3) as a result of low $T_{1/2}$ and low $^{110m}$Ag initial deposition level. Samples were indeed collected in the vicinity of the main contamination plume as access to the most affected area was restricted by Japanese authorities. It also has been detected in the finest fraction of the Soil 4 sample. Fig. 4 describes the distribution of $^{110m}$Ag and $^{137}$Cs radionuclides in the different grain size fractions of Soil 1 and Soil 2 samples. Activity distribution is similar for both radionuclides and the major part (from 33% to 65%) of their activity was measured in the finest fraction (<63µm; Table 3). We could therefore not detect any difference in the particle-size effects of adsorption between both radionuclides. This finding is crucial in order to use the $^{110m}$Ag/$^{137}$Cs activity ratio to track the dispersion of contaminated particles in catchments, as the finest particles are the most susceptible to be eroded and redistributed (Motha et al., 2002).

Experiment 2 – Migration in soil (Profile)

Activities measured in the uppermost part of the soil profile (Fig. 3) confirmed the low mobility of $^{134}$Cs, $^{137}$Cs and $^{110m}$Ag (Table 4). The bulk of their inventories (~80%) were contained in the first layers (0 – 8 mm) and decreased rapidly with depth (Fig. 5).
The $^{137}$Cs total inventory reached about 417 kBq.m$^{-2}$ and the relaxation mass depth $h_0$ was 7.1 kg.m$^{-2}$ for $^{137}$Cs (Fig. 6). This value is close to the one found by Kato et al. (2012b) in a cultivated soil (9.1 kg.m$^{-2}$) in the vicinity of our sampling site. This value also remained in the same order of magnitude as in several cultivated soils investigated by Ivanov (Ivanov et al., 1997) near the Chernobyl Power Plant (ranging from 5.6 to 9.1 kg.m$^{-2}$).

In order to compare the behaviour of both radionuclides, we calculated in the same way the relaxation mass depth for the $^{110m}$Ag and found 7.6 kg.m$^{-2}$ with a total $^{110m}$Ag inventory value of 1 kBq.m$^{-2}$, showing that penetration of both radionuclides in the soil was similar.

Our results are consistent with the ones provided by other studies that investigated the behaviour of the same radionuclides in soils. Alloway (1995) showed that $^{110m}$Ag is not mobile as it is the case for $^{137}$Cs (Sawi-iney, 1972; Spezzano, 2005) and they both remain in the uppermost 5 cm of the soil (Handl et al., 2000; Kato et al., 2012b; Shang and Leung, 2003).

We investigated the migration of radionuclides in a profile of bare soil, but the transposition of those results to soils covered with vegetation is not straightforward, as the radionuclide interception and migration processes were reported to play a major role in forested environments (Kato et al., 2012a). Furthermore, Martin et al. (1989) reported that during the first months that followed Chernobyl fallout, $^{110m}$Ag required more time to migrate from grass to soil (50% reduction) than $^{137}$Cs (90% reduction) due to foliar leaching. However, this effect should have remained limited in Fukushima, as most cultivated soils (i.e., paddy fields) were found to be bare when atmospheric fallout occurred in March 2011.
These results confirm the low mobility of $^{110m}$Ag in cultivated soils. As it remained concentrated in the first layers, it could be rapidly redistributed across hillslopes as a consequence of runoff and soil erosion.

C. Behaviour of $^{110m}$Ag in rivers

Experiment 3 – Activities in sediment sequences accumulated in reservoirs (Dam Sed 1 & 2)

The pH measured in the four investigated rivers varied between 5.0 and 6.0. It was demonstrated in the literature that pH plays a major role on $^{110m}$Ag behaviour in both soil and water. Its mobility in soils (Khan et al., 1982; Shang and Leung, 2003) increases when pH raises and its affinity for suspended particulate matter (SPM) rises when pH exceeds 7, to reach maximum values at a pH of 9 (Fukai and Murray, 1974; Murray and Murray, 1972). In contrast, $^{137}$Cs was shown not to be affected by a pH variation (Adam et al., 2001). Because the observed pH values remained significantly lower than 7, $^{110m}$Ag behaviour and $^{110m}$Ag:$^{137}$Cs activity ratio were not expected to be affected by pH variations in Fukushima rivers.

Analysis of the two sediment profiles (Dam Sed 1 and 2 – Fig. 3) tends to confirm the similar post-depositional behaviour of the radionuclides (Figs. 7 and 8). Their activities were concentrated in the top of the profile (Tables 5 and 6), and most likely resulted from deposition of sediment eroded after the initial radionuclide fallout in March 2011. Before the FDNPP accident, $^{137}$Cs activities in sediment were generally lower than 100Bq/kg in Japanese soils (Fukuyama et al., 2005), which corresponds to activities found in deeper layers of sediment accumulated behind Tetsuzen dam (Dam Sed 1). Higher contamination in lower layers in the second profile (> 500Bq/kg) most likely resulted from contamination
originating from upper levels during sampling (scraping). However, this will not impact the conclusions drawn from this experiment as they strictly focus on the observations made on the top layers.

In Tetsuzen dam sediment (Dam Sed 1), a lower activity was measured in the surface layer than in the underlying layer suggesting that a minimum of two significant erosion events had supplied contaminated sediment to the reservoir by November 2012 (Fig. 7; Table 5). Also, $^{110m}\text{Ag}/^{137}\text{Cs}$ activity ratio remained constant for these layers. Furthermore, a significant difference in particle size between the first two layers and the third layer confirms the occurrence of an intense erosion event, probably during the dam release that was carried out during the period of heavy typhoons that took place during summer in 2011. Based on this information, sedimentation rates were estimated to 20 cm yr$^{-1}$ in Tetsuzen dam, and to 5 cm yr$^{-1}$ in Takanokura dam.

The similar percentage of radionuclide inventories found in the successive layers and the calculation of constant $^{110m}\text{Ag}/^{137}\text{Cs}$ activity ratios confirmed that $^{110m}\text{Ag}$ and $^{137}\text{Cs}$ have a similar behaviour with regard to their adsorption onto soil particles and sediment. This result was expected owing to the high distribution coefficients reported in the literature for both Cs and Ag (Ciffroy et al., 2001; Fournier-Bidoz and Garnier-Laplace, 1994). $K_d$ values remaining in the same order of magnitude were estimated for both radionuclides in winter and summer (i.e. $K_{dCs^{137}} : 0.1-100$; $K_{dAg^{110m}} : 1-100$). Ciffroy et al. (2001) also quantified the kinetics of the adsorption and desorption of these radionuclides in freshwater systems, and concluded to their similar behaviour. Fournier-Bidoz and Garnier-Laplace (1994) and Garnier et al. (2006) showed that $^{110m}\text{Ag}$ has a strong affinity for river SPM and especially for their
clay fraction. A large number of studies demonstrated that Cs has the same behaviour
(Ojima et al., 1965 in Ancelin et al., 1979; Garnier-Laplace et al., 1994). He and Walling
(1996) confirmed that $^{137}$Cs affinity increases with specific surface area in the case of a
uniform contamination of the soils. Guéguéniat et al. (1976) reported similar results for
$^{110m}$Ag.

**Experiment 4 – Impact of typhoon and snowmelt**

During the three successive sampling campaigns that followed the succession of snowmelt
and typhoon events, the inventories of $^{110m}$Ag and $^{137}$Cs measured in sediment drape
deposits collected systematically at four sampling points in the upper part of the Nitta
catchment (Fig. 3) showed similar patterns (Fig. 9). As expected, samples collected close to
the catchment headwaters (SDD 1 and SDD 4) showed a decrease in contamination
throughout time, probably due to the flush of the most contaminated material during high
water flows (Table 7). In contrast, the samples collected at the 2 downstream locations
(especially SDD 3) were associated with a slight temporal increase in contamination of $^{137}$Cs
that may be explained by a supply of upstream – more contaminated – material. This
explanation is consistent with the fact that $^{110m}$Ag:$^{137}$Cs activity ratio measured in sediment
remained in the same order of magnitude as the ratio measured in soils of this upper part of
the Nitta catchment (Table 8).

An alternative explanation to the activity increase observed throughout time is that the grain
size of particles could have changed from one campaign to the next, explaining the observed
differences in contamination. Calculation of surface specific area (SSA) shown in Fig. 9 shows
that this might be the case for sample SDD 3 (with an enrichment in fine particles
throughout time), but not for sample SDD 2 (SSA remaining constant in time).
Because of different experimental conditions (non-homogeneous fallout deposition and high radionuclide activities), our results plotted on Fig. 10 do not show a power function as found by He and Walling (1996) but they display instead a linear function for both $^{137}\text{Cs}$ ($r^2 = 0.89$) and $^{110m}\text{Ag}$ ($r^2 = 0.91$) that is strongly correlated with the SSA.

This tends to confirm the similar behaviour for both radionuclides, although particle-size effects and fractionation could have occurred, given that erosion and transport in rivers are obviously selective to finer particles. Consequently, these results confirmed the relevance of using of $^{110m}\text{Ag}:^{137}\text{Cs}$ activity ratio to investigate the dispersion and redistribution of contamination along rivers.

Conclusions

Silver-$^{110m}\text{Ag}$ is an anthropogenic radionuclide that is produced continuously by nuclear power plants (NPP) in normal conditions, but investigations regarding its behaviour in the environment are rare despite the potentially important radioecological implications of its accidental release into the environment. In the Fukushima NPP post-accidental context, the interest to conduct field studies on the behaviour of $^{110m}\text{Ag}$ was reinforced by the fact that initial deposits displayed $^{110m}\text{Ag}:^{137}\text{Cs}$ activity ratios that varied across space within the main radioactive contamination plume. This study showed that $^{137}\text{Cs}$ and $^{110m}\text{Ag}$ were strongly sorbed by the finest particle fractions (i.e., clay or silt), and that the bulk of their inventory was stored in the uppermost part of soil profiles (i.e., <2 cm), confirming that the in-depth mobility was not significant during the two years following the accident. In addition to this fine particle reactivity, we showed that soil erosion and sediment transport in catchments that mobilize preferentially the finest particle fractions did not induce different fractionation effects for both radionuclides. This study therefore confirmed the relevance of
using this ratio to track the dispersion of contaminated material along coastal rivers draining this area. In future, due to the rapid decay of radiosilver and its initially relatively low fallout level, extraction methods could be used in order to measure precisely radiosilver and continue to investigate its behaviour and the dispersion of contaminated sediment along rivers.

Acknowledgements

This work was a part of the TOFU (Tracing the environmental consequences of the Tohoku earthquake-triggered tsunami and Fukushima accident) project, funded by the joint French National Research Agency-Flash Japon (ANR- 11-JAPN-001) and Japan Science and Technology agency/J-RAPID programme. H. L. received a PhD fellowship from CEA (Commissariat à l’Energie Atomique et aux Energies Alternatives).

Figure 10

The figure shows a scatter plot with data points for Cs-137 and Ag-110m. The plot correlates specific surface area (m²·g⁻¹) on the x-axis with ¹³⁷Cs activity (Bq·kg⁻¹) on the y-axis. Two regression lines are present, one for Cs-137 and another for Ag-110m, indicating a strong positive correlation between specific surface area and activity.

- The regression line for Cs-137 has an R² value of 0.8938.
- The regression line for Ag-110m has an R² value of 0.914.
